### CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

W EDWARD GALLIE, President IRVIN ABELL, Louisville President Elect

Committee on Arrangements
HOWARD PATTERSON Chairman, FRANK GLENN Secretary

## PLANS DEVELOP FOR 1946 CLINICAL CONGRESS OF THE AMERICAN COLLEGE OF SURGEONS

THE announcement in the March issue of SURGERY, GWNEDLOGY AND OBSTITEZES of the definite plans for holding the 1046 Clinical Congress of the American College of Surgeons at the Waldorf Astoria in New York City from September 9 to 13 has been greeted with enthulasm. A large meeting and exception ally keen interest are assured. The four years without a Clinical Congress have been years impressively lacking in a focal point for intensive study of trends in surgery, and surgeons every where are eagerly anticipating the resumption of the annual meeting

Progress does not stop when there is no Congress, of course, but the application of new techniques and ideas is delayed when there are no opportunities for the meeting of minds that a large international conference affords. The Clinical Congress makes a convenient annual miliepost by which to calculate and to evaluate advances in surgery and it provides a spur to progress through this function and through its inspirational infinite.

Surpeous need the stimulation that comes from directly hearing of new developments from the lips of those who helped to initiate them. They need opportunities to ask questions, to participate in discussions, and to observe other surgeons at work, both in the local hospitals and on the motion picture screen. The latter teaching device in particular is becoming increasingly profitable and popular as more good medical films are produced and at the Cinical Congress ample opportunity is provided for surgeons to view the newest and best pictures.

The Clinical Congress, as the previous article indicated, will be the usual five-day session, embracing forums on fundamental surgical problems panel discussions, clinical conferences, symposis, demonstrations, films scientific sessions, hospital conferences, exhibits, and the formal Presidential Meeting and Convocation. This year the Convocation will be a particularly momentous event, since in addition to the initiates of the current year there will be present a great many of the accumulated total of a 7,44 surgeous who were recived into fellowship in absentia during the four war years in which no Congress was held. It will also be an occasion of reunion for the Fellows, both new and old, many of whom have been over seas on military duty much of the time since the Boston Congress in 10.11.

The new officers of the College who will be in stalled at the Presidential Meeting and Convocation are Dr. Irvin Abello Louiville, as President Dr. Leland S. McKlitrick of Boston, as First Vice President and Dr. F. Philairy Collions of Atlanta as Second Vice President. The Presidential Address will be given by Dr. W. Edward Gallie of Toronto the returng president.

Plans are progressing for making the programs of all of the scientific sessions, morning alternoon, and evening provide the most comprehensive delineation possible of advances in surgery and tated sciences during the five years succe the 1941 Congress. The various surgical specialities, ophetalinology orthoploarly properties of the pr

Advance registration and hotel reservations are urged upon all who plan to attend the Congress. May, 1946

# PENETRATING CRANIAL WOUNDS A SUMMARY OF METHODS USED IN MANAGEMENT

#### Collective Review

J E. WEBSTER, M D and E. S. GURDJIAN M.D F.A C.S Detroit, Michigan

#### INTRODUCTION

ECENT literature pertaining to the management of cranial wounds in World War II has added important new information to the older concepts of treatment. The reports which are continually reaching publication serve to advance our knowledge and unify opinion. Any general review of this subject must consider the present incompleteness of information. We propose merely to aummarize the experiences of various observers to date in the interest of consolidating reports and to emphasize the application of the measures employed in war surgery to related cavillan injuries.

This summary is devoted mainly to a con skleration of penetrating wounds caused by bullet or shell fragment missiles (Fig. 1) Injuries of this class produced by forces peculiar to high velocity represent a unique neurosurgical problem Penetrating types of civilian cranial injuries of low velocity present quite different requirements in care. The difference in the decrece of destruction of scalp skull and cerebral tissue dictates the differing principles in surgical management. The radical measures employed in the débridement of high velocity wounds are not required in the less destructive, low velocity civilian injuries (hammer blackjack rocks, knives car door handles, electric fan blades stationary objects) distinction is made at the outset since only brief consideration is given to the usual low velocity type of penetrating wound as encountered in dvilian practice.

From the Department of Surgery, W yne I all ensty College of Medicine and the Department of Neurosurgery. The Detroit I'e-ceiving and Grace Hospitals, Detroit.

The survey includes observations made in 300 patients with crankal wounds produced by missiles of high velocity and treated in the 36th General Hospital which was located in Italy and in France Because of the hospitals location all types of wounds were observed including one group of 40 cases of late wound débridement in German prisoners of war (210 211 212) The civilian patients with guishot injuries of the brain were treated at the Detroit Receiving Hospital and Crace Hospital during a period of 90 years.

Before the principles followed in the care of patients with cranial wounds in World War II are described a brief review is made of the history of the care of war wounds in general and of those historical factors and opinions marking progress in the care of crantal injuries. The time periods are divided for consideration as follows Early World War I Interim and World War II periods The neurosurgical methods and technique employed in World War I are reviewed in some detail for comparative purposes. Brief consideration is given to the applicable physics of tissue destruc tion produced by high velocity injuries. A group of nonmilitary gunshot wounds of the brain was included in order to evaluate methods of treat ment used in civilian practice.

#### HISTORICAL EARLY PERIOD

#### ARLY PERIOD

It has been reported that the first use of gun powder by the English was in the Battle of Crecy in 1346 (100). The poisonous nature of the wounds so produced was described by Ciovanni da Vigo (1460-1525), surgeon to Pope Julius II

who stated that all gunshot wounds are not only who stated that an guiname would are not con-confined and burned (requiring mont sppice continuo and outness trequiring moss arrange tions) but also poisoned by the powder (requiring account of the powder (requirement of the p dentation); and hence difficult to cure" (120) "He advised contenting the wounds by means of boiling elder oil or actual cautery " Braums II eig possing enter on or action causes)

a surgeon of Strasbourg and others agreed with
this plan during the 15th century (86) A new era was thus begun in warfare attended with "super stitions terror aroused by the use of the new seapons which produced remarkable noise and Response name products remaind the same and fine upon discharge and profound acute and late. effects upon human tissue. In the attempt to re lieve the bod) from the process of poisoning the openings of entrance and exit and track of the openings or critically and can and can are the ball were incised the wound dilated by fents or other means, terebuthinates or boiling oil poured into it irritating compounds and oint ments applied and it was only after the wound ments appared and at how only acted the revolution and considered to be fully purged of its remoin and foul humor by the extensive suppurative action thus kept up that electrization was permitted to be established" (95)

The 16th century marked the beginning of a revolutionizing treatment of war wounds in Scheral Alphonse Stenza surgeon to Paul III from 1534 to 1549, in the early part of his career held the same viers as Weig and Vigo as to the pousonous nature of gunshot wounds. He made important improvements in wound management, advising upon the search for balls, their extrac tion, and upon the subject of dresungs (80) Later in this era Ambrose Paré (144) leading suggests of the Renaisance and founder of military as a science and art," discontinued the early practices, merely dresung of Itah supported the doctrines of Park which were published in a treatise on gunshot wounds (80) Leone Botal, and Fallophus "at once embraced the views of these eminent matters and Felix Wurz of Germany about 1576 wrote against the employment of too complicated instruments for the extraction of balls deprecated trephning for depressed gunabot fractures of the skull ad ised the discontinuance of the application of fatti subriances to gunshot wounds and musted upon the antiphlogratic treatment (80). In this century Botallus (17) described foreign bodies in the brain reognized but was not drained even though it Complicating cerebral abscess was mas recognized that death would result by ea pectant treatment Opinion was confused as to the window of removing bone fragments from fractured skulls it was believed whe to bore if fisture in the skull was present. Dyes were used

[a flammation arising in the track of the projectile (5)]. The term "debridement" was used to de arise this method forward management. For a sampler and of loss french practic. For a sampler and forward interest in an out of the french practic flow a sampler and published in 1910 and entitled filled. Inflammator and Garabot Woomle. Something can be done do when the river of the property of the french of the projection of the french of the pro

ing Hester (90-128) referring to cranel wounds in the 18th century made the following observation (Guardon wounds which affect the cranism are for the most part attended which affect the cranism of the concustom of the interarble spiner very slight or the concustom of the interarble spiner very slight or the concustom of the interarble spiner very slight or concustom of the interarble spiner very slight of the concustom of the interarble spiner but the concustom of the interarble spine of the cranism of the vens and arteries born, in which case the cut are asset to be concustomated based has no vent, nor can be created the concustom of the cranism be extracted. Death therefore must be the issue unless prevented by

The Napoleonic Wars which ended in 1815 marked new Progress in the care of gundot Arice Cooper as stating that in (84) guoted Sir War between 1828-1813 that in the Penlinshir cared from the practical experience of that war form the practical experience of that war fore.

Baron Larry (117) in his memours of the Na poleonic campaign in Russia. Germany and France clearly stated the principles which he followed in the treatment of cranial wounds. He reported that m a wound of the head accompanied by a fracture of the cranium should the fragments of bone be displaced and driven internally so as to injure the bram and dura mater the trephine is indespensable. When the foreign body which has caused the wound is enclosed between the pieces of bone or has penetrated into the interior of the cranium-the case is again one which demands the application of the trephine. Finally, when the surgeon is assured of the existence of effused fluid under the cranium, this instrument is also indicated. He believed that the operation should be performed as early as possible recognizing that "inflammation is generally established in the meninges after the first twenty four hours suc ceeding the occurrence of the injury (84) held similar views, subscribing to operative treatment based upon observations made in the Peninsular War After suggesting that a cranial wound be examined with a blunt, flat probe to determine the extent of damage, he raised the question 'What is to be done when depression and breaking down of the inner table have been ascertained? There can be no heatation-that in all such cases the trephine should be applied al though no symptoms should exist, with a view to anticipating them. The old doctrine, it may be said in regard to fractures generally is revived in these cases but on a principle with which our predecessors were not sufficiently acquainted. A patient very often survives a mere depression of the skull he may and occasionally does, survive a greater depression of the inner than of the outer table but it has not been shown that he ever does survive and remain in tolerable health after a depression with fracture of the inner table when portions of it have been driven into the dura mater The result of my experience has rendered it imperative to remove at once all portions of bone or foreign substances which have materially injured the dura mater although no symptoms of compression should be observed. Hennen (92) emphasized the importance of trephine for com pression without fracture. Where there is no wound the case becomes dubious and we are reduced to act upon probability founded upon gestures of the nationt, his sensibility to pain upon pressing on a particular spot, or we may be guided by what the French surgeons place much depend ence on viz. the existence of paralysis, which is most commonly on the side of the body opposite to the compressed portion of the brain

Fig. 1 Examples of penetrating missiles removed from the brain. They bone chips and particles of clothing are present on the surfaces of the shell fragments.

The military operations in Algeria (1846) in Schleswig Holstein (1849) and in the Crimean War (1854-56) presented opportunities to test again the applicability to military practice of the great improvements accomplished in the civil practice of surgery in Europe since the termination of the war in 1815. The practice generally, of 'what has been styled conservative surgery' characterized the interlude between wars (95)

The trend toward conservatism in cranial sur gery as well as in general surgery was demon strated by the views expressed and by statistics which began making their first appearance Longmore (95) pointed out that a gunshot wound of the head had previously been an indication in itself for the use of the trephine, that earlier in the 10th century trephine was used for injuries with out fracture. Such preventive trephine has been proved to be useless as well as dangerous and is universally acknowledged not to be an admissible operation. He stated that the majority of the English surgeons after the Peninsular War limited the use of trephine to fractures with depression causing interruption of cerebral func tion, fractures with bone indriven into the cerebral tissue and where an abscess had developed and was capable of evacuation. The trend was to confine the practice of trephine 'within still narrower limits. Stromeyer (95) an experienced German surgeon reported 41 gunahot iractures of the skull with depression Of the 41 cases, 7 terminated fatally Of the 34 patients who lived, only I was trephined and this was the only case of trephining which gave a favorable re sult in all three campaigns (Schleswig Holstein 1849) Stromeyer had earlier advocated trephine but stated in his Principles of Military Surgery

that he had abandoned the Practice (183)
Macleod (122) in Anotoned the Practice (183)
in the Crimen' Aported that of patients with
the treatment of Secretarial wounds the treatment of the study wounds the treatment of the study wounds the treplane
was employed only 28 times and 24 of terplane

dorsement of the modern treatment of ex in
in mre cases (122)

Macleod reported that the teaching of all thoroughly to remove only such pieces of bone as could be got at with the forceps and which were could be got at with the forceps and which were locally and even generally to bleed, if need be, enjoin when there says as fear of inflammation to constitution of the second applies but, if possible to the special senses also by an and to country the property of the special senses also by an and to country the property of the special senses also by an and to country the strength of the special senses also by an and to country the property of the special senses also by an and to country the special senses also by an and to country the special senses also by an and to country the special senses also by a special senses also be a special senses also be a special senses and the special senses also be a special senses and the special senses also be a special senses and the special senses also be a special senses and the special senses also be a special senses and the special senses are special senses as the special senses are special senses are special senses as the special senses are special senses. The special senses are special sense

This extract is not only expressive of the opin on of a single individual but may be regarded as embracing the views of the majority of surgeons of this period (80).

Information resulting from the War of the Re bellion in the United States (126) raised some doubt as to the reasonableness of the conservative conclusions formed by the continental surgeons. Reports showed that successes attended surgical intervention in crantal wounds. published a comparison of the results of trephin ing compared with those of the expectant plan of treatment. Of 160 patients on whom the trephine Gross (80) was emblosed to be cent died and of 223 with kerious conditions treated by expectancy 74 per cent deel Of 126 cases in which fragments of bone were clevated or extracted, or foreign bodies mere removed 55 per cent were fatal. After all operations of every kind the rate of recovery was 41 per cent. By the conservative or espectant plan only 15 per cent lived, making in favor of operative interference 16 per cent of recoveries. Gross (80) reviewed the plan of treatment of crantal wounds proposed by Neudorfer (137) who was so prejudiced against the trephine that he not only did not use it himself but advised that it be excluded from the armamentarium of the arm) surgeon. He summanized the views of Stromeyer (183) Propost (155) Legouet (119) Williamson (217) Demme (51) and Matthew (125) In about

ing the confusion of opinion. He pointed out that the trephine is emplored by surgoon of Lnown experience and high reputation for widely different lenous and symptoms—that with one, its results have been invariably fatal and a positively contraindicated under all circum stances. With another the results have been so favorable that its application is not restricted to: navourse true to appearance to an extraction of lesions (Progot) Legocal Williamson) The variance in the experience be tween the American surgeons and those shood ras ascribed by Longmore (95) to the fact that the former did not restrict the application of the trephine to otherwise hopeless cracs and to the difference in the effect of the old round ball and the sharp mine bullet.

ion Toward the end of the 19th century advanced to Opinion formulated the following policy in the best stances are force of lower from the stances are force of lower or forces as well as the stances are force down and evidently peak stance or where the press upon—the or forces substance or where absence as manifestly exists in any stance or where absence as an interest extended by an analysis of the mana at the wound itself storded by any proper operation but all other cases harm will sorting to be considered by abstancing force in them sorting to long with the force of the word of the stances of th

can War reported that conservative surgery is the pride of the modern doctor on the field of battle. The stacks of amputated limbs that con stituted such a gruesome and constant sight after every battle during the Civil War will never be seen again on the field of battle where modern surgery is practiced. The first aid dressing properly applied at the right time constitutes in the vast majority of cases, almost sure protection against infection of the wound. Prophylaxis has largely taken the place of operative surgery in the field. Our recent expenence has demonstrated that the small-caliber rule is the most humane weapon If the wounded survive the immediate effects of the injury the prospects of recovery are good. What a contrast with the experience of the surgeons during the Civil War only thirty five years ago At this point artiller, was still little used and high explosive bombs and land mines were unborn instruments of destruction Records of the period indicated that shell frag ment wounds were invariably infected.

Prior to World War I, von Bergmann (203), Papaullon (143) and Doyot (55) recommended operative treatment for penetrating cranial wounds, employing an open method. Zoege Von Manteuffel (205) in 1906 reported upon the inadequacy of the conservative management when used in the Russo-Japanese War (1904 5). In the open treatment, after débridement of the communited bone, neither the dura nor scalp was closed which usually resulted in hemiation of the brain and frequently the death of the patient. When this treatment was used in the Bulgarian Turkish War (1972-73) by Colmers (39) 70 per cent of all tangential gunshot wounds of the head with minury of the brain died of infection

#### WORLD WAR I-GENERAL CONSIDERATIONS

Surgeons in World War I were imprepared to treat the type of wounds which they encountered because of two major changes in the instruments for wounding. The first was the increased velocity of missiles and the second was the frequent use of artillery fire in place of ride injury to the extent that the ratio of gunshot wounds to those produced by artillery fire was reversed (18)

The concept at this period of a conservative management of war wounds of all types even with the knowledge of asepsis proved to be a failure. Established methods resulted in a high incidence of morbidity and mortality due to infection (66 18) Since antiseptics were in vogue, early use was made of various solutions to cleanse the 358

The critical of the late of dails in the fatal case were absent of the brain, encephalitis, and meningitis.

A policy of early operation debridement, and complete closure of the cranial wound was recommended by Barany (11 12 13) Willeams (216) and Cushing (44) being first suggested in 1913 by Clairmont (36) and Colmers (39) Barany (17) particularly grasped the importance of the removal of devitalized tissue and closure of the dura and scalp without drainage. Cushing (44 127) en nounced a surgical policy in dealing with this type of wound in 1918 advising a catheter suction method of debridement. Ultimately this technique became a standardized procedure. In view of this fact, a detailed description is presented of the "Directions to Neurosurgical Teams as out lined by Cushing (127).

It was first recommended that every scalp wound be considered as a potential penetrating wound of the skull and brain, a principle founded upon the observation of Hippocrates Nullum copilas vulnus contemnendum. As a part of the general attitude toward all wounds, an all or nothing plan of debridement was recommended The observation was made that patients with penetrating wounds of the brain were able to tolerate transportation rather well before opera tion but poorly during the first few days after operation. It was held that craniocerebral cases "in more or less shock need not undergo a period Local anesthesia combined of resuscritation. with morphine was suggested as the most suit able anesthesia (40) The directions stated that the chief source of the high mortality in cranial wounds was infection—infection of the meninges direct infection of the brain leading to encepha litis, and infection of the ventricles."

The principle recommended in the operative technique was the removal of the contaminated wound margins and of all foreign material from the brain along with devitalized brain tissue. The "tripod incision was advised to provide exposure of the underlying bone defect. The directions stated only in the case of large scalp defects is the switching of flaps necessary for closure, and it is questionable whether this is desirable. technique suggested for the exposure of the brain track was the use of three or four perforations about the akuli defect and the tilting up and removal of the bone "en bloc. It was advised to leave as small a bone defect as possible - a quarter of an inch margin beyond the defect suffices. The area of dural laceration should not be en larged. The debridement of the contused brain and track can best be carried out with production of the least damage to the brain by gentle suction and irrigation with a soft rubber catheter. The catheter detects indriven bone fragments as well

as does the finger and then these can be picked out with delicate forceps. Metallic fragments of small size are surprisingly well tolerated. No mention is made in the technique outlined concerning the closure of the dura. Horrax (102) and Rand (158) have stated that it was usually not closed since, as the latter reported, the incidence of sepais where the latter reported, the incidence of sepais where the dura was closed was disproportionately high." Use was also made of dichloramine T in oil as an antiseptic 'particularly suitable for infections in the central nervous system tissues.'

Craniocerebral wounds were classified into o special groups based principally upon the type of damage produced. These groups and their per centage of mortality were as follows (127) (45)

1 Wounds of the scalp (about 5%)
2 Cranial fractures without dural penetration

(10%)

3 Cranial fractures with depression and dural penetration but without extrusion of brain (20%)
4. Wounds usually of gutter type with brain

extruding and indriven bone fragments (30%)
5 Wounds usually of penetrating type with in

driven bone fragments plus metal (40%)

6 Wounds types 3 and 4 with penetration of bone and metal opening the ventricles (50%) 7 Craniofacial wounds or orbitofrontal or

temporopetrosal wounds in which the ethmoid or petrosal sinuses are open (60%)

8 Perforating or traversing wounds (70%)
9 Extensive bursting fractures with fatality
usually due to trauma rather than infection

(100%)

Harvey (88) recommended that every case in Group 2 should be explored and trephined that if the pathway from the external wound to the fracture is continuous then infection will, in many cases,-even with the simple depressed fracture without dural penetration-lead to meningitis or an abscess in a contused adjacent cortex. The statement was made in Harvey's report that patients in whom the dum was closed did badly. As a general policy it was advised to allow the dura to remain open and in addition to drain the scalp with a small rubber wick to prevent damming back of the infection which would lead to meningitis or a cortical abscess. It was noted that in the gutter type of wound classified as Type 4 the probability of infection was of the greatest degree and it was held that wounds in which infection of the scalp or its intra cranial contents is problematical should be left open for free drainage. Penetration of the ventri cle was found to result in a high mortality (Cushing noted no recoveries in patients in which the ventricle was penetrated by a metallic projectile.) The management of wounds involving the orbit consisted of enucleation of the destroyed eye, and removal of the indriven bone fragments from the bony orbit and the pulped brain from the track. Blateral decompressions were sometimes performed on extensive bursting fractures, but recovery was unusual

The mortality rate including the results in all types of wounds with dural penetration was 37 5 per cent, being reduced from 54.5 per cent in the first group of petients to 28.8 per cent in the last group (44)

#### BRAIN ABSCESS, FUNGUS, AND MENINGITIS— WORLD WAR I

The report by the Surgeon General (127) summarizing the complications observed following penetrating wounds of the brain stated that the principal cause of death in patients with head wounds after return from oversess was abacess of the brain The abscesses frequently occurred in cases in which there were retained foreign bodies. In 210 cases Cushing encountered 8 fnstances of brain abscess within a few weeks of injury (24) In 37 cases studied by Sargent and Holmes (160 170) the overwhelming frequency of brain abscesses in the first three to an months after injury was shown 28 patients developed abscesses in that period, whereas the complication appeared in a 6 to 9 month interval in an additional 7 cases. The latest appearance of brain abscess was in the eighteenth month. The history of World War I recorded that multiple abscenses were found to be practically always fatal, and recovery from a brain abscess without a capsule was extremely rare (127) It was stated that the primary stage of abscess formation was one of septic encephalitis for which surgical procedures would give no rebei. The ideal time for operation was after the formation of the capsule.

It is sometimes difficult to determine just how drainage of pus should be accomplished or whether simple aspiration with a needle should be made" (127) The procedures used for the drainage of abscesses varied in magnitude from the use of an osteoplastic flap to that of a simple trephine opening. It was noted that the best results in the treatment of this complication were obtained in the drainage of single abscesses with capsules. A second opinion stated that consideration of all the facts fustifies the conclusion that the most favor able time for accurately placing a drainage tube in an abscessed cavity is when the pus is first discovered. It is often possible to empty the abscess completely at this time, and there may be very little subsequent discharge. The drainage tube

should be fixed to the scalp and should not be removed until drainage has discontinued (1:1). Brain abscss unrelieved by operation was considered to be fatal yet the vast majority of patients (0.7 % in Surpert and Holmes series) deed after the drainage of pus (1:8).

Fungus was observed to be one of the most frequent complications following the drainage of cerbral abscers, and the mortality was high. A fungus was the "fresult of an undrauned abscrawith or without hydrocephalms or an energhalitis." The notation was made that the treatment of the condition of fungus is as a rule unestifactory. It was beld important that any associated accumulation of pus should be drained (527).

#### RETAINED FOREIGN BODIES-WORLD WAR I

Prior to World War I, a conservative attitude was taken toward the removal of foreign bodies within the cranial cavity as pointed out by Pilcher (152) in an excellent review of this subject. Sir Benjamin Brody in 1828 (20) approved of this policy. Later however cases were reported in which the foreign bodies within the brain substance were removed. In the Medical and Surgical History of the War of the Rebellion (126) 85 cases of bullet removal were reported. Andrews (4) in 1868 and Wharton (214), 10 years later advocated the removal of retained bullets when they were localizable and accessible. Morris (133) in 1887, Papallion (143) in 1894, and Hewett and Lidell (93) in 1881 held this same view Phelps (150) in 1906 stated, There is probably no authenticated case in which the bullet left in the brain substance has failed to work muschief DaCosta (46) in 1910, wrote 'that practically every lodged bullet (in the brain) constitutes a fatal condition and it should be re

moved if possible, even if there are no symptoms." Following the use of roentgen rays in visualiz ing and localizing intracranial foreign bodies, first suggested in 1896 by Stubenbord (152 184) re moval became a more practical procedure, and was more widely practiced. (Rouvillois [163], Cazamun [34], Regard [159] and Villandre [200] recommended removal of all foreign bodies.) As a result it was observed that a relatively small number of retained foreign bodies were discovered in patients with head injuries following their re turn to the United States after World War I (137) In two series aggregating 392 patients with head injuries at general hospitals, 19 had intracranal foreign bodies which were either pieces of metal or bone fragments. Frazier and Ingham (63) reported our percentage of retained foreign

bodies which is 10% is almost identical with that bounds which is 10/0 is annow identical with their recorded by Sargent and Holmes 164 in 1567 occases, or 11%. Of a series of 9 patients with re tained missiles treated by Bagley (9), 7 were operated upon Four had an associated abscess with a positive culture. In 3 cases there appeared to be no signs of brain disturbances from the foreign bodies and in these the cultures were

Frazier's (127) indications for the extraction of foreign bodies were as follows Foreign bodies causing encephalitis or epileptic senures should be extracted those apparently latent should be left alone. This opinion was subscribed to by Bagley (9) Demmer (52) Von Eiselsberg (204) and Coleman (38) Wagstaffe (206) noted that the incidence of epileps) was alightly higher among those with retained foreign bodies

# INTERIM PERIOD DETWIEN WORLD WARS I AND IT

Interest in penetrating cranial wounds alack ened after reviews were made of war experiences techniques evolved were considered as eatisfactory. The possibilities in neurological surgery revealed by the war focused attention upon civilian neurological problems. A rapidly broad ening field resulted in the training of a number of general surgeons into neurological surgeons who became experts in this particular speciality and in due course of time trained others

There was thus available at the start of World War II a considerable number of trained neurosurgeons as well as a rapid means of training additional men through abort courses or by pre ceptorahip In contrast to World War I, this was a major advantage true in all specialties when medicine mobilized for war

A second advantage at the start of World War If lay in the improvement in transportation and its means of mass production adequate methods formerly used were replaced by streamlined methods employing a greater number of men, units, and vehicles and the air as a medium for transportation. Expeditious evacu ation from the point of injury to hospitals for definitive treatment, recommended early by Ton nis (191) was constantly a foremost considera tion although it was subject, at times to mair mountable difficulties. This factor was of major importance in the management of cranial wounds

Research during the interval between the wars had resulted in the introduction of sulfonamide drug therapy in 1936 with evidence of astonishing results in the treatment of infection

Sulfonamide therapy was observed to be par 36 r ticularly efficacious in the treatment of infections caused by the streptococcus of the beta hemolytic type the Lancefield Group A hemolytic organ isms, the meningococcus pneumococcus and gonococcus Staphylococcal infections, however were not benefited to the same degree The mode of action of this drug by bacteriostasis per mitted the control of injection of the central nervous system following cranial nounds in a high percentage of cases.

A widening knowledge concerning body chem istry fluid balance anoxia blood replacement the treatment of shock and wound healing added significantly to the effectiveness of the surgical

The pathophysiological conditions of the brain resulting from trauma were more clearly under stood Many contributions to the literature both of an experimental and clinical nature, had been made during the interval between World Wars

An important contribution pertaining to the improvement of the technique for the debride ment of penetrating wounds was made by Horrax (99) in 1940 He suggested that such wounds be treated by more radical excision with coning of the track of devitalized tissue in place of the catheter suction debridement. This suggestion later put into practice in World War II proved to be a significant aid in treatment.

Under these circumstances, neurosurgeons in Order these chromosances, hemosurgeons in general faced the cranial wounds produced in World War II, adequately prepared organized and equipped.

## MECHANISM OF INJURY FROM BULLET AND OTHER PENETRATING WOUNDS

Wounds from high velocity bullets and shell fragments are relatively recent experiences in military surgery It is only during the past 60 years that high velocity bullets have come into use, and only since World War I that high velocity shell fragment wounds have been noted with frequency. Whereas a low velocity weapon may traverse the body mainly with injury to the im mediate neighborhood of the track high velocity missiles cause extensive damage also at a distance from the track in the tissues . It is not uncommon to see organs bones and other tissues severely damaged at some distance from the bullet passage. Usually blood vessels and nerves are more resistant because of their elasticity and thus they may escape anatomic injury On the other hand, vessel injury may be seen at a distance from the missile track by splash of the blood against the

intima with longitudinal tears. Thrombosis, sec ondary tear with hemorrhage from necrosis, or aneurysins, may ensue.

The agents of injury especially concerned in this study include bullet and shell fragments, as well as certain tools and utensils used in low velocity penetration of the cranual cavity most instances, pointed bullets are seen in mili tary injuries, whereas round nosed missiles are found in civil practice. In practically every in stance, bullets used in military practice are facketed with a core of lead in the center Jacketed bullets usually retain their shape except at impact with bone at velocities of 2 500 feet per second or more. In civilian practice with soft bullets, it is common to see the missile shattered into many fragments at impact. In rifle injury the muzzle velocity of the bullet may be 2,000 feet per second or more, and the rifling causes the bullet to rotate about its long axis approximately 1,000 times per second with a velocity of 500 or more feet per second. Sir Victor Horsley (104) has attributed the explosive effect of high velocity missiles to the rotation of the bullet about its axis rather than to its muzzle velocity. This will be discussed in greater detail in the next few paragraphs in connection with recent experiments pertinent to the problem

Shell iragments may have extremely high velocities, and it has been estimated that they may travel from 4,000 to 5,000 feet per second near the site of explosion. They vary in size and shape and they are more likely to become contaminated with clothing, hair and helmet lining which may be introduced into the cranial cavity Whereas bullets usually cause a neat wound of entrance and possibly also a clean wound of exit, shell frag ments may cause large, lacerated wounds of en-In accordance with the velocity irregular tears or bruises of the struck area may be seen. Frequently the fragments remain in the cranul cavity It is interesting to note that in certain instances tiny fragments may be dispersed within the cranial cavity Among this group of cases there may be instances of relatively little brain damage.

Low velocity penetrating wounds of the skull and brain may be produced by kulfe blade, are pick, glass, umbreils end and many other tools or every day objects. Ordinarily infection is seldon introduced into the cranial cavity and this may be partly explained by the fact that during the period of thrust dirt particles are held back as the object enters the scalp and skull.

A very important difference between high velocity and low velocity injuries is to be found in the type of damaged brain about the missle track. With high velocity injury there is online at long distances, whereas with low velocity belief wounds and with stab and similar penetrating wounds, there may be no damage except for the track in the tissue. Wilson (218 219) fates that

track in the tissue. Wilson (218 210) states that the wounding effect depends upon, first, the amount of energy transmitted to the times second the velocity of transmission third the direction of energy and fourth, the density of the tissue." The amount of energy transmitted to the tissues depends mainly upon the velocity of the weapon. Mass times the square of velocity divided by 2 is the formula to calculate the amount of energy With velocities up to 2,000 feet per second the amount of energy utilized, as evidenced by damage done by the musile, is proportional to the square of the velocity. The time of transmission of energy to the tissues is ex tremely important and this depends upon the velocity of the injuring object. The shorter the time of transmission, the greater the horse power expended in a unit of time. Callander (30) states that with extremely high velocities the wounding effect of the missile varies as the cube of the velocity and only as a single power of the mass. The density of the tissues is also important. Wilson (218, 219) working with gelatin solutions, concludes that the energy of the missile is dispersed inversely to the square of the percentage density that is in a 5 per cent gelatin solution explorive effects are approximately 4 times as great as in a to per cent solution o times as great as in a 15 per cent solution and 16 times as great as in a 20 per cent solution The velocity imparted to the there about the track is important in that but of timue bone fragments, and other organic matter may act as secondary missiles with more ex tensive injury. If a bone is struck by a high velocity mustle near the wound of exit, there may be extensive shattering with skin loss. Ordinarily the elasticity of the skin protects it from extensive tours and lacerations. Whereas a discreet wound of entrance and exit may be seen with a high velocity bullet injury of the thigh the skinned extremity of the same experimental animal will be shattered to bits by the same missile injury (31)

The polping effect at a distance from the mismental work. Sir Victor Honley (104) attributed this to the explosive effect of the bullet in tapessage through the tissue. He thought that the rotational activity of the bullet, rather than the mustle velocity caused the explosive effect. Recently Black, Burns, and Zuckerman (15 20)

have shown that when a high velocity pellet with out rotational acceleration enters a gelatin cube it causes a tail splash at the entrance. As the missile traverses the gelatin there is a marked swelling and enlargement of the cube to 4 or more times its previous size This is caused by the formation of a temporary cavity which almost completely disappears as the pellet passes through and the gelatin cube returns to its former size Black, Burns and Zuckerman (15, 230) emphasized that rotation of the bullet on its long axis in rifle in juries is not the cause of the explosive effect. However they admit that a change in the posi tion of the built as it enters the tissues or as it passes through the same because of precession, may alter the dimensions of the track, but the temporary cavitation about the track is due to radial velocity imparted to the walls of the track by the passage of the musile Butler Puckett Harvey and McMillan (23) have studied the passage of spherical missiles with the use of a microsecond x ray apparatus with which x ray pictures may be taken in one-millionth of a second or less. They have shown that in its passage through the cranial cavity the missile causes a large temporary cavity which expands rapidly and undergoes several pulsations before the tissues return to premjury dimensions The passage of the misule causes high radial velocity imparted to the tissues about the track which in turn causes the temporary cavity Within the cranial cavity this produces an intense increase in intracranial pressure with maceration and pulping of tissue at long distances from the missile track and extensive disorganiza tion of the cranial bones with fragmentation and separation at suture lines. In order to show the role of the intracranual contents in such injuries the following experiments were carried out. A cat, under anesthesia, was struck in the head with a sphere 4/32 of an inch in diameter with an im pact velocity of 3 800 feet per second There was extensive fracturing of the skull with fragmenta tion and separation at suture lines. In another cat the skull was cleansed of the soft tissues and brain and a similar injury merely caused a wound of entrance from 6 to 8 tumes larger than the sphere and a small wound of exit only a little larger than the missile. The comparison of the perforations of the skull in this instance with the extreme fracturing and fragmentation in the ex periment in which the intracrunial contents were intact is most convincing

Wounding by shell fragments has been ex tremely common in World War II Only 15 per cent or less of the crantal wounds entering the evacuation hospital were from bullets. The great

est majority of the bullet wounds of the head 363 caused death on the field of battle Shell frag ments vary considerably in size shape, and con tour They may travel at extremely high and then again at low, velocities. The irregular con tour causes extensive laceration and the missile is more prone to carry dirt and foreign matter into the body The mode of injury is essentially the same as with a high velocity bullet if the fragment is stopped by the body while travelling at a high speed Severe lacerations of the brain with pulping of the cerebral substance along the track oc curs In many instances penetrating shell frag ments remain in the cranial cavity a few may perforate.

In penetrating low velocity wounds such as those caused by knife blade umbrella end or fan blade there may be a tearing of important vascular channels and infection may be introduced into the cranial cavity The brain about the track of the missile is not pulped and therefore can successfully resist certain amounts and types of infection.

The mechanism of sudden death following pen etrating wounds of the brain has been investi gated by Polis (156) and Webster and Gurdjian (200) It was observed to be due to a paralysis of the vasomotor and respiratory centers in the medulla With an increase in the velocity of an injuring bullet, there was a corresponding in crease in the severity of the physiological effects

# METHODS OF TREATMENT—WORLD WAR II

Certain generalizations regarding the treatment employed in World War II warrant mention as a preface to the details of operative technique used in high velocity wound management these is the attitude toward patients with crantal wounds. The treatment of this group of patients was undertaken not only from the standpoint of rehabilitation for further duty but as a humani tarian obligation Regardless of the severity of the wound the courage required in the collection of the patient from the point of injury the time employed in primary care, or the efforts con sumed in effecting postoperative recovery conscientious effort was rande to accept that re sponsibility by all personnel involved philosophy on the part of surgeons nurses company aid men and hospital corpsmen was a significant factor in the excellence of the care which these patients, in general received

The campaign in Africa and in Italy early established the value of the neurosurgeon in the Evacuation Hospital and set a pattern which settled any doubt as to where the treatment of

cranial injunes should be carried out, in either a last moving or a stationary type of warfare. Auxiliary surgical teams supplied the personnel for these bespitals if neurosurgeous were not available. Following operation and after a period of observation in the Evacustion Hospital for from 5 to 10 days the neurosurgical patient was evacuated to a "Neurosurgical Center a general hospital so designated, for late postoperative care and convilescence General bospitals were deployed as near to major activity as possible, reaching such positions for operation within one month after an invasion

A second practice of major importance was the modification of neurosurgical operative tech nique to war wound needs following the suggestion made by Horrax (90) in 1940. The availa bility of electrocoagulation and efficient suction units resulted in the adoption of more radical measures in débridement. It was also recognized that "brain areas could be wholly or partially removed without detriment to the individual (00) By the older technique "a careful but necessarily slow and tedious dehridement of the wound in the brain was accomplished, an average of two hours being required for the serious, deeply penetrating wounds (99) By modernizing the technique, operations were performed rapidly with time saving short cuts. Skillful co-opers tive amouth functioning teamwork usually assisted the surgeon. Ability experience and confi dence acquired in previous training implemented the surveon's desire to accomplish his purpose as quickly as possible. Laborious attempts at hemoatasis were replaced by rapid coagulation slow irrigation debridement was replaced with total suction debridement of all devitalized tissue. Modern electrical apparatus provided necessary illumination From the preparation to the closure of the scalp all but essential manipulations were eliminated.

#### PRIMARY DEBRIDEMENT

All cases with scalp wounds were considered as cases of penetrating wounds of the brain unless proved otherwise and all but the obviously fatal wounds were explored (Fig. 2). Following neurological examination, routine roemigen studies of the shull were made. Stereoscopic views were held to be exsential by some (32) but the pressure of work or failure of the patient a co-operation often made any additional studies impossible. Viscalization of the bone fragments and actual count was attempted. In general, the neurosurgeon was able before operation to visualize the path of the penetrating missile and the degree of bone injury

and imbedding of the bone (ragments. Individus) surgeons varied in their standards for determining the inoperable patient, but in general, except when the pressure of work was too great, all but the obviously fatal wounds were explored. Par ticular attention was given to the selection and operation of patients with increased intracerebal bleeding who failed to respond to respectation and those with intraventricular wounds (80) Intensive resuscitation measures were employed consisting mainly of the transfusion of whole blood and plasma, the employment of warmth rest and pain relief and the provision for ade quate pulmonary ventilation. Craig (41) has recommended the use of oxygen to help reduce increased intracranial pressure The high inddence of associated injury (approximately twothirds of the patients observed by Gaynor and Gurwitz (67) presented wounds in addition to that of the head) required consideration in planning treatment

Eden (58) has stated "that there is no doubt that the surgeon who first operates on an open wound makes or mars it-ideally the initial operation should be the final and complete one The principle of an all or nothing debridement stressed by Cushing (127) was followed in principle although not always attained. The scalp was prepared by complete and thorough shaving and washing about the wound with soap and water for 10 minutes. The use of an antiseptic was elective. Local infiltrative anesthesia was used whenever possible, supplemented by the use of preoperative morphine analgesia. Caums (24) has objected to the use of morphine, while Horrax (101) believes it may be used in widely open compounded wounds. Slemon (178) used local anesthesia in 56 per cent of penetrating bram wounds with a basal narcosis induced by alopon (gr 1/) scopolamine (gr 1/150) and huminal (gr 3) When a general anesthetic was required, the intratracheal administration of ether was preferred. Sodium pentothal has been used with soc cess (129) but caution is required to control the depth of anesthesis (67) Supplementary pentothal anesthesia was used in 15 per cent of the patients operated upon by Munslow (136)

Long curved meditons of the scalp which the cluded the total excision of the wound of entrance were made in place of the 'tripod type formerly med. They were planned to permit an adequate blood supply to the scalp. The incition was designed with the purpose of securing scalp closure at the end of the operation. The perioranism was carefully removed from the bone defect after debufdement since its later use for dural grafting

Fig. 2. Civilian patient presenting a gutter type wound of the right parietal area by a 38-calibre revolver selfinflicted. She was operated upon 6 hours after injury Through curved inclaims the area of bone defect was ex-

posed, fragments of bone and pulped brain these were removed. The dura was débrided. The dural defect was re paired with a fascia lata graft. The bone defect was subsequently repaired with tantainm.

was possible. The bone defect was enlarged with a rongeur Frequently a bur opening was necessary adjacent to the point of entrance Fragmented bone was removed as well as any additional bone to expose adequately the injured dura and brain. More severe fragmentation of the inner table has often been observed (57) The en bloc' method of bone removal was usually not employed After the excision of damaged dura, the track of the missile in the brain was debrided by suction removal of the devitalized cerebral tissue, blood clot, and bone fragments. A coring of the track to normal tissue was frequently accomplished under direct vision with a lighted retractor as suggested by Horrax (99) The utmost care was employed to spare injury to the cortical vessels. Foreign bodies were extracted if at all possible the electromagnet being employed by some Enter ing the ventricle was avoided but not at the sacrifice of incomplete débridement Saline solu tion was used in irrigation of the track and wound although not advised by Munro (8) doubt existed as to whether all bone fragments were removed the finger was gently used in the large tracks to feel for the fragments The dura was closed by means of a graft of pencranium temporal fascia fascia lata or preserved cadaver dura Cushing silver clips were sometimes used In place of sutures by Havnes (89) In some in stances, to conserve time the dura was not closed. Two layer interrupted silk closures were attempted in all cases Relaxing incisions were not used. In cases of severe scalp loss over a defect of skull and dura a flap of scalp was used to cover the defect. The bare pericranium was im mediately grafted (split thickness) An osteo-

plastic flap has been recommended in the small clean wounds associated with persisting neurological signs for exposing an intracerebral hemor rhage (25) The local instillation of sulfanila mide penicillin or combinations in the brain track and in the overlying wound was done by some surgeons (26 58 171) Cairns (26) stated that in recent brain wounds (up to 72 hours old) penicillin can be applied in a powder (5 oco units of penicillin per gram of sulfanilamide) followed by primary closure of the wound ' In 129 cases so treated fatal infection developed in only 2 He stated also that sulfanilamide and sulfathiazole have been used in some hundreds of brain wounds with no reactions of the kind de scribed by Watt and Alexander (208) Following operation all patients were treated systemically with sulfadiazine or penicillin the chemotherapy begun at the time of wounding or shortly there after being continued. It was discontinued when the wound was healed

#### DELAYED PRIMARY DÉBRIDEMENT (24 HOURS—10 DAYS)

The observation first made in World War I that patients with crantal injuries are transportable with greater safety before rather than after operation resulted in a late primary debridement of cranial wounds being done in many instances (7) Unlike patients with delayed wound care in World War I who travelled well but ultimately died of infection many of these patients survived. Generalized infection was usually prevented by chemotherapy and the localized encephalitis was reduced in degree and even controlled. Thus patients in this class in

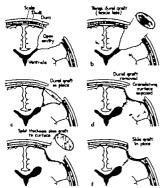

Fig. 3. Open exteriorization method of treating brain aboves with graft of facial tata in patient with meanive loss of scalp, skull, and dura. The aboves is totally dibbided a temporary facial star grift is sutrent to the instact dural edge, which prevents lexings of the cerebrospiral finial and bernation the scalp is not closed penicillin solution is injected through the graft into the cavity. The temporary graft is removed in from 5; to so days and a split thickness graft applied to the area, the scalp being conserved for caminoplasty.

general, did not present wounds with an extruding brain and meningitis as formerly

The surgical management of this type of wound was similar to that described under primary debridement. Success depended upon total wound excision and thorough debridement of the brain track. A dural graft was not used. The local in stillation of penicillin for several days post operatively in conjunction with its systemic use, aided in wound healing Terian (Russian) (188) reported experiences with delayed operations. In 71 per cent of 102 cases, operation was under taken within 20 days after injury usually on the sixth to eighth day Eight of the patients died 6 of these had meningitis at the time of operation. The fatality rate of 182 cases without meningitis was 1 1 per cent. The conclusion was made that "the time interval after wounding is less im portant in cramocerebral injuries than meticulous and specialized care in investigation, operation and after treatment." The dura was not closed in any of these cases and the scalp edges only were apposed over the wounded brain by a lex

Delayed primary débridement of cranlocarbral wounds differs from earlier recommendations made at the start of World War H. Hornar (10) t stated that after from 24 to 48 bours 'the whole wound should be packed widely open under vasclined game or rubberized tissue and the vasulting fungus allowed to beal by granulation and recode." Schnize and Betzendahl (173) also suggested that after 48 bours the penetrating wounds should be treated as a brain abscess with 'open drainage."

#### SECONDARY DÉBRIDEMENT (10-40 DAYS)

Healed wounds presenting retained bone frag ments within the brain were frequently encount ered [Italy, 13.4% France, 31 9% (210)]. These were usually the result of necessary haste due to lack of time at the primary debridement when the all or nothing' rule was not followed. By means of roentgen studies the fragments were accurately localized and after evening of the bone defect a conservative secondary track exploration with removal of the bone chips was performed This policy has been followed by Eden (58) Schwartz (174) Schorstein (171) and Rowe and Turner (165) When necessary a dural graft was applied with safety since the wound was not grossly contaminated as in patients requiring late primary debridement. The scalp was closed. Tonnis (101) reported that all cases which had been provisionally operated on for tangential wounds of the brain showed prolapse, with spinters of bone in the depths of the brain. The prolapse was reduced by repeated lumbar punctures. Under local anesthesia, the opening in the skull was then enlarged the depths of the wound freed from dead matter, and any remaining splinters of bone exposed and withdrawn. The wound was kept open by a Mikulicz tampon soaked in prontosil, to assure the free escape of ducharge. It was noticed in the wounds which had not been tampered with at the front that prolapse of the brain had been hindered by the splinters of skull At both the primary and the left in place secondary debridements, the attempt was made to remove completely all organic material, consisting mainly of bone chips and of the inorganic material when possible.

In general, the management of retained metal life fragments followed the principles set forth by France (1sr). Some (6sr ano) have reported that ragged metallic fragments were found to be iden with organic material—tiny bone fragments, harr and belimet linking—and cultures of such missiles, as well as of bone fragments usually re sulted in the growth of pathogenic organisms. Not only the size of the metallic foreign body but the irregularity was of importance. It is reasonable to view the presence of retained shell fragment particularly as a threat to a future inflammatory, complication. Such findings usually do not occur when the penetrating missile is a smooth intact bullet.

#### CONSIDERATION OF BRAIN ABSCESS

The term brain abscess, as used in this article describes a purulent collection or collections within the brain substance which followed track injury produced by a penetrating missile. An incidence of 16 per cent occurred among 206 patients (in cluding German presoners of war) with penetrat ing wounds of the dura and brain observed by Webster Schneider and Lofstrom (210) The incidence among American wounded was 14 per cent in Italy and 19 per cent in France (210) Cairns (27) has reported an incidence of abscess formation in 25 per cent of patients in whom wound débridement was incomplete or performed late A similar proportion was estimated by Rowe and Turner (165) In Ascroft s series (25) 75 of 202 patients developed brain abscesses under his care. Eden (25) however had but 1 case at tributed to the fact that cases were received at an earlier stage and before they had been operated on by the general surgeon

No case of abscess was noted among patients in whom the dura was not penetrated (210). The abscesses occurred early and were associated with wound infections and frequently with hernias or fungl. Usually they were not encapsulated but were localized by reactive inflammatory tissue of a dense quality at the site of the original débridement and also in the track produced by the mi. sile or the bone fragments. Komean ky (114) noted that in 69 per cent of cases brain abscesses 'were due to an infection of the wound. In 28 per cent they were cortical and in 52 per cent intracerebral. They occurred 2 or 3 weeks after injury.

Several surgical methods of management have seen employed in treating this type of complication (210). The techniques were based primarily upon a complete reddendement of the wound and the abscess by means of excl. ion of all inflammatory tissue and the abscess levell the latter being removed by suction. The resulting wound was then treated by (1) closure of the scalp (2) closure of the scalp about a tube for the instillation of penicillin (3) extenorization of the cavity (21) and (4) extenorization with a temporary dural erait (Fig. 3).

Fig. 4. This patient presented a brain absects associated with a retained bone fragment and an infected wound. Management consisted of excision of the wound and the absects followed by the daily instillation of penicillin solution through the scalp. Primary healing occurred.

Webster Schneider and Lofstrom (210) con cluded that an early abscess following a penetrat ing wound of the brain must be treated by complete removal and not by drainage without excision (Schulze and Betzendahl [1-3] in 1040 recommended simple open dramage ) and fur ther that no single technique was applicable to all situations. There were situations in which it was possible to close tightly the overlying scalp after wound excision and extirpation of the abscess (174) This is a technique similar to that used for late purulent and nonpurulent undebrided wounds which has been successfully practiced with or without the local use of penicillin Drainage of the abscess followed by the local instillation of peni cillin through a small rubber tube placed into the cavity has been employed by Eden and Cairns (25) and Lowe and Turner (165) The latter use a technique of complete evacuation of the abscess and the removal of all foreign bodies establishing drainage by use of a Penrose sheath or rubber tissue drain or occa lonally a soft rubber

tube In addition, a Dakin tube is introduced into the depths of the cavity. At this tune in mixture of dry penicillin and sulfanilamide is placed in the cavity. In contradistinction to the ordinary practice of leaving the wound entirely unsutured, it has been found leasible, with the aid of chemotherapy to carry out a nearly complete closure in many cases. Webster Schneider and Lofstrom (aro) found it difficult either to aspirate through a small rubber tube or to meet penicillin solution and were obliged to remove the tubes in 48 hours and inject the solution through the scalp (Fig. 4).

In a number of unstances these methods were not successful namely when the frontal or masted sinuses were involved when the scalp was edema tous and necroit when there was a large scalp defect through loss of tissue when débridement of the abscess was not as complete as desired. A special form of management was then used which

was as follows After the usual complete redebridement of the wound and excision of the abecess, the remaining cavity was covered temporarily by means of a graft of fascia lata sutured to the debrided dural edge. This temporary graft and the mirrounding bone edge were covered with vaseline gauge, the scalp wound being left open Penicillin solution could be injected daily through the graft mto the site of the abscess. At the end of 15 days, the fascial graft was removed and the underlying brain was prepared for a split thickness graft, which was applied from 5 to 7 days later without disturbing the scalp Any mobilization of the scalp was avoided in consideration of the subsequent cranioplasty which would also complete the

scalo dosure The temporary dural graft of fascia lata served two purposes first, it prevented cerebral hemia tion, and second, it prevented cerebrospinal fiuld leakage. Following the debridement of an abscess with disturbance of all the barriers to infection meningitis may result or diffuse infection may be present at the time of the attack upon the abscess. In either situation postoperative cere bral swelling herniation and fungus formation may result if the debrided area of the abecess has been extenorized without a covering A nack or drains may be extruded. If the scalp has been closed over such a defect in the dura there may be extrusion of the brain subcutaneously. The use of a fascial graft as a temporary covering prevents such herniation until the infection is brought under chemotherapeutic control. Lenkage of cerebrospinal fluid into the frontal sinuses may also be controlled by the temporary graft, which is removed when the bram has scaled itself about the line of normal dura. A temporary graft was used as it was held to be unwase to bury a faschi graft in an unclean wound because of the risk of necrosis of the graft and continued wound infection. However, Rowe and Turner (165) have nocessfully burded fascula fraits in unclean women's

Lebendenko (118) reported a mortality of 101 per cent in the treatment of 211 patients with brain abscess, and his notation concerning the technique of operation was that 'if the walls of the abscess are intact, the abscess is removed in (David and Ferey [47] found that 24 per cent of 82 patients with fungus ded ) Komeamky (114) reported a fatality rate of 18 per cent in surgically treated cases of brain abacess. Bukulov (Russian) (22) reported that 16 8 per cent of the patients with abscess died when treated at a specialized evacuation hospital. The mortality in Ascroft a cases was 25 per cent (25) Rebater Schneider, and Lofstrom (210) found that 17 per cent of the patients with abscesses treated by various methods died. The mortality among those treated by the use of a temporary dural graft (mainly frontal sinus wounds) was 18 per cent.

#### CONSIDERATION OF WOUND INFECTION YUNGUS, MENINGITIS

The occurrence of wound infection was observed to be dependent upon several factors. These included the season of the year and the associated weather conditions the terrain on which the fighting took place the mobility of the war fare the speed of evacuation the number, type, and severity of the casualties the degree of blood loss and the extent of the replacement. These influences, and probably many more such as the number of dressings and the exposure of the wounds, had a bearing on wound healing. It was of interest to compare the incidence of wound infection in patients in the Italian and French theaters with that in a group of German presoners of war A high incidence of wound infection oc curred in the latter group when certain known fac torsincluded (1) late primary wound débridement and (2) inadequate or incomplete wound debridement. On a rapidly moving front under ideal weather conditions (late summer) the POW pa tients were treated by the same chemotherapeutic routine as wounded American soldiers. The comparative statistics were as shown in Table II (018)

The companson warrants the conclusion that the prime factors in preventing infection are early and thorough wound excision Caims (27) found

Incidence of retained bone fragments

that in fresh cases operated on by neurosur geons the incidence of postoperative intracranial infection was only 3,7 per cent Rowe and Turner (165) have reported that approximately 15 per cent of the head wounds showed some degree of Slemon (178) found an infection rate of 129 per cent. Plans for wound care must be designed to meet the complications arising from infection delayed and hasty debrudements. The average time interval between wounding and operation VAS 276 hours (maximum 5 days minimum 6 bours) in patients reported by Slemon (178) The importance of wound infection to late sequelae

Although fungus of the brain was a frequently has been shown by Ascroft (7) encountered condition (210) this complication did not constitute the problem which it appeared to present in World War I By means of chemotherapy a spreading encephalitis was controllable and fulminating cerebral swelling and extrusion of the cerebral tissue was prevented The streptococcus organism responsible for rapid and fatal infections in World War I was particularly vul nerable to sulfonamide and penicillin therapy Cauras (27) reported that the staphylococcus aureus is a frequent wound contaminant proved by the bacteriological examination of wounds during the Sichian campaign. The Russians (25) found that only 2 of 300 head wounds were sterile and that a large proportion of deaths were due to anaeroble pathogens (Report by a Committee of

The principle of closing the dura following Soviet Scientists, 1943 [25]) primary wound debridement prevented post operative hermation Instances of extrusion of the brain with a separated and infected wound were frequently the result of an underlying cerebral abscess. Relief was obtained after excision of the fungus and total debridement of the associated abscess usually pocketed under the extruded

A meningins which may have been present was usually completely controlled by means of con tinuously administered penicillin or sulfadisaine Exception to this occurred when the

invading organism was drug resistant, being then usually of a gram negative type (Friedlander s bacilius) An unsubsiding meningeal infection was also found in the presence of a cerebral ab-

On failure of a patient to improve normally scess which sustained it following primary debridement with clinical evi dence of infection as the cause of the failure, three steps were taken the chemotherapeutic program was revised to meet the new demands, efforts were directed at proving the presence of an abscess and cultures were made of the cerebrospinal fluid (210)

## SULFORANIDE AND PENICILLIN THERAPY AND BLOOD LOSS REPLACEMENT

Both sulfadiaxine and penicillin were used in the treatment of the cases presented by Webster Schneider and Lofstrom (210) Those patients who were observed in the Italian Theater were in the main treated with sulfadiazine while those in the French Theater received penicilin The inci dence of wound infection in each series of cases did not vary significantly being 19 8 per cent and 23 6 per cent respectively Of the group of pa tients with cranial wounds complicated by brain abscrsces, the first 15 were treated with sulfadia zine (penicillin being used only when sulfadiazine failed to control the infection) The latter 18 were, in general treated with penicillin An appraisal of the results (mortality) based upon the type of chemotherapy employed showed that in the group of 15 cases treated with sulfadingine 4 deaths occurred Penicillm also failed to control these fatal infections when used after the inci ficiency of sulfadiazine was apparent Among the

18 patients who received penicillin 5 deaths re sulted. Three of the 18 patients were given sulfadiazine treatment when the penicillin failed and all presented favorable outcomes. In this limited analysis, an outstanding difference in the effectiveness of these drags did not seem to exist. Others have observed the superiority of penicillin (8a) Slemon (178) observed an incidence of in fection of 31 2 per cent in 32 patients treated by the local application of sulfathuasole while the rate decreased to 9 2 per cent in 184 cases treated locally with penicillin and a sulfa drug both groups sulfadiazine was used systemically Pilcher (154) in over 1,000 experiments has studied various aspects of the chemotherapy of intracranial infections. Among many observations, the following are the most significant

r Sulfathiazole may produce severe or even fatal convulsions when applied to the brain and abould never be used (Contrary to clinical ex

perience of Cairns [25])

2 Experimental staphylococcal meningitis was markedly benefited by oral sulfadiazine but not by oral sulfathiazole

3 "Penicillin when given intravenously was ineffective in staphy lococcal meningitis, but when given intrathecally it greatly reduced the mor tality rate.

4. Penidllin given intrathecally in normal dogs produced variable degrees of mild irritation and pleocytosis in the cerebrospinal fluid, apparently dependent largely moon the amount of impurity in the preparation of penidlin.

The healing of open cerebral wounds con taminated with staphylococcal organisms has been augmented by the local use of sulfadiatine but was apparently unaffected by local sulfathia sole or local penicillin. (Contrary to clinical observations)

6 Chemotherapeute agents given systemically have benefited experimental cretinal absesses only in so far as associated meningitis, if present was benefited. In other words, our experiences indicate that such drugs probably do not gain access to well-encapsulated infection of the central nervous system.

The use of either drug it appears, is effective

only in proportion to the thoroughness with which the source of the infection is irradicated by surgical measures.

Blood replacement must be recognized as an

Blood replacement must be recognized as an important factor contributing materially to the control of infection and the production of satisfactory wound heating. A lowered hemoglobin and hematocrit were frequently encountered in spite of previous transfusions in forward installa

tions, particularly in patients with associated injuries. The latter occurred in 36 per cent does group of patients with canalal wounds (130) and in 38 per cent on the general hospital, liberal use was made of whole blood transfurions. Secondary operations were performed after normal levels were established and further replacement was continued as needed. German prisoners were observed to have a secondary anemia greater than that found in the American wounded, and this may have been an added factor related to the common observation that wound healing in the former group was notorfoully boor.

#### SUMMARY AND RESULTS

Comparison of the types and results of trest ment in groups of patients with war wounds re quires qualification as to the point in evacuation where the observations were made. The highest mortality of cranial wounds occurs on the battle field itself Little information exists as to the character of these early fatal wounds. The neares the front line the higher the mortality (25) The casualties who survive wounds for at least 8 hours reach evacuation hospitals field hospitals, or similar units for definitive surgical treatment. Death serves to process the wounded during the early hours of infury The greater number of neurosurgeons available in the American army resulted in the performance of operations upon severe and extensive wounds. In other armies the 'more hopeful of the "bad (178) lesions were operated upon after minor injuries with absent or minimal neurological signs and then the more severe penetrating wounds, in order of their severity were treated. Some observers (24 130 138) have pointed out that the purpose in the neurosurgical treatment of cranial wounds of war is not life saving but the prevention of infection in survivors of such wounds. The process of primary debridement, toward that end, which is usually per formed in the Evacuation Hospital is none the less associated with a significant mortality Secondary debridement at a General Hospital, again m survivors, is also attended by an oc casional death. Any evaluation must, therefore, be made only in consideration of the corresponding time and place relationships, and the type of cases selected for operation. This is strikingly true in a review of penetrating wounds of the brain in civilian life In this class, one-half of the patients who are brought to the hospital die within 6 hours of admission

Information is now available concerning the care of cranial wounds of World War H at Ameri-

can evacuation hospitals and at British casualty ergrounds of scalp and skull. clearing stations or mobile field units Table IV summarizes reports which have appeared in the

The following patients with war wounds con adered in this review were observed by Webster recent literature Schneider and Loistrom after reaching a general hospital having in most instances been previ ously operated upon at evacuation hospitals. Most had survived their injuries and operation for from 5 to 10 days. There were 198 patients with penetration of the dura and brain and 62 with compound fractures in which the dura escaped penetration Forty German prisoners of war have not been included in the statistics ex cept in the summary of orbitocranial and cerebellar wounds There were 84 petients with wounds of the scalp requiring neurological observation The mortality was 6.4 per cent among 260 patients (Ital) 146 cases mortality 6 8% France, 114 cases, mortality 6 1%) The wounds were caused by shell fragments in 75 per cent of the patients and by bullets in 14 per cent in 11 per cent the cause was unknown A summary made in several groups and based upon the type of management required in treatment rather than upon the type of pathological damage pro-

Wounds of the scalp (84 cases - o dealks) The duced is given as follows patients in this group reached the general hospital usually because of a significant degree of per sistent headache which warranted further rest and Wound infection occurred in 15.4 per cent of these patients, which delayed early return to duty taken of 8 patients who presented symptoms and

was found It was not unusual for patients in this group to require neuropsychiatric attention their complaints being due to psychoneuroses.

Wounds without dural penetration (62 cases-I death) The dura was inspected at the time of the removal of the depressed bone fragments in all but II of this group of patients. Extradural hemorrhages were found in 3; and subdural hemorrhages in 2 1 of these patients manifested the complication by Jacksonian convulsions. Four patients presented major neurological disability in 3 of these the dura was observed to be normal. One patient died trephining being done at the time of failure. Autopsy showed that death was due to diffuse intracranial injury An encephaloque to uniuse musicamai minty fur encepumor graphic study was made of a patient in this group Trepanation at the site of a linear fracture was not routinely performed, although it was said to

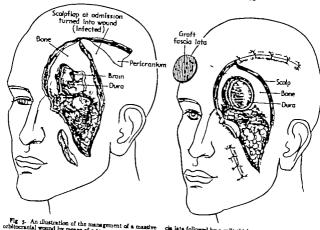

Fig 5. An illustration of the management of a massive orbitocranial wound by means of a temporary graft of fas-

cia lata followed by a split thickness graft to the defect.

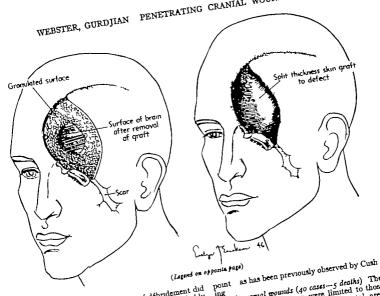

pericramium, temporal fascia or fascia lata was used to close the dural defect when necessary For example the dura was closed in all but 2 cases of the 50 cases in this group the condition in these 2 cases not permitting further expenditure of time at operation Among this group of 50 cases, a "preserved" dural graft was employed in 5 patients. The dura was obtained from cadavers and preserved in formalin and then alcohol (177) The observation of damming back of infection" when closure of the dura was employed, as re ported in World War I was not made

Patients with gutter type wounds almost uniformly sustained massive anatomical damage to the scalp skull, and brain This type of wound was less commonly observed, probably because of the fact that survivors were less frequent. The observation that the pathway for infection is maximum is supported by the fact that brain abscess developed in 9 patients of this group, an incidence of 43 per cent. The policy of tight closure of all wounds at primary debride ment regardless of the degree of infection con trary to that of World War I in which the wound

was left open for free drainage, appears to be well founded It is of interest that relaxing increons were not employed in the care of gutter wounds with major loss of scalp Closure was effected when mobilization of the scalp falled, by means of a flap swung into the craniotomy site, and a bare area of pericranium was left for grafting

The depth of track damage was usually greater upon penetration by a metallic missile. The potential contamination was also greater because of the fact that fragments, especially those larger than I centimeter bore organic material upon their surfaces. This was true particularly of ragged missiles in contrast to smooth bullets. Shell fragments may be covered with tiny bone particles adhering to the surface. The threat of later complications would appear to be considerable when such fragments are retained. A policy of removing all accessible metallic, as well as bone, fragments was followed when such missiles had not been removed at primary operation.

Survivors of wounds involving the ventricles were infrequently encountered. Contrary to the observation in World War I opening of the

ventricle per se in the course of debridement did not significantly increase the mortality probably because of the protection afforded by chemotherapeutic substances Control of infection was possible, even when the ventricle was entered in the course of débriding a complicating cerebral

Few patients with perforating wounds sur The principles in management were abscess. similar to those for the less severe penetrating injuries The wounds of ent, entrance and of the The dura was closed by means of grafts if necessary Only I patient entire track were debrided was found to survive a perforating injury involv ing both hemispheres which had been caused by a

Orbitocranial wounds (40 cases - 5 deaths) The cases placed in this group were limited to those which involved the orbit and the frontal area of the skull and they were considered sepa of the skull and they were communicated in the special type of management of this often necessitated group of wounds has been reviewed in detail (111) The injuries of this type numbered 40 and were divided into two groups-Group I num bering 20 patients who presented severe destruc tive anatomic injuries to one or both globes in addition to the skull and brain injury Group II also numbering 20 patients, but these presented wounds which involved the orbit and brain with varying degrees of physiological injury to the contents of the orbit. Massive wounds involving the orbit and frontal area with associated injury to the paranasal sinuses could not be treated by conventional methods of debridement and closure because of the loss of tissue A suitable method for treating this type of injury was the employment creating this type of injury was the employment of a temporary graft of fascia lata to close the dural defect. The graft was removed after 15

Fig. 0 fan mane injury or the right fronts sobe. A sig-om, intracerebral clost, as removed from the missile track. The injury was caused by a broken off blade of an automothe fan connected to a 10 voit circuit and consequently

running at a much higher speed. There was no immediate tenance at a moon suggest specific and was no movement.

days and a split thickness graft was then applied to the granulating area of involvement (Fig. Particular attention was given to the total de bridement of the sinuses by removal of all de vitalized tissue bone fragments, clots and sinus mucous membrane. mended radical debridement in wounds of the Schoratein (171) recomfronto-orbital region and the employment of a soft paraffin gaure pack in the open wound. A plaster-of-parts skull cap was then used as a rou tine dressing

An osteoplastic flap used for exposure of the frontal fossa was found to be of value in wounds with penetration produced by small metallic fragments which entered the orbital roof and the frontal lobe at the base of the skull. This exposure allowed debridement at the aite of the bony in jury and of the brain as well as the repair of the dura either by suture or graft. Distortion of the frontalarea through loss of bone was thus avoided. In 5 of the 40 cases in this group brain abscess developed an incidence of 12 5 per cent.

Wounds turning the corebellum (10 cases—1 It was observed that wounds of the cerebellum were infrequent. Ten cases (an incl dence of 3%) were encountered (213) War I reports indicate an even lower percentage of 54 (6 cases in 1 108)—(127) In 9 of the 10 pa of the cerebellum, and they were caused by shell fragments in all except 3 cases. In 3 instances the wound of entrance was located in the neck and the associated cerebellar injury escaped attention. The infrequency of cerebellar wounds is probably due to a low incidence of survival among patients with wounds involving the posterior portion of the

brain. Other factors probably include the protected anatomical location of the cerebellum and the adequate covering afforded by the steel helmet which was available in World War H. Thu type of injury, which presents the possibilities of rapid and serious complications, demands ex ploration as early as possible and is thus a probcm for the evacuation hospital neurosurgeon There was I death in this group of patients 8 presented minimal neurological defects.

### MILITARY CIVILIAN CORRELATIONS AND CONCLUSIONS

In civilian practice bullet wounds constitute at most all of the high velocity injuries in military experience only 15 per cent of cranlocerebral in-Juries were caused by bullets, as seen in a general hospital, and while wounding by shell fragments is unknown in civilian practice 75 per cent of the cranial cerebral wounds in war belonged in this class (210) The majority of bullet wounds in military practice are latal because of the velocitics and size of the missiles. Most bullets for was use are encased in a metallic casing and have a pointed nose A great many of the civilan bullets are round noted Frequent fragmentation and dispersion of fragments through the area of impact are common with the latter. In view of the lower velocities in civilian bullet wounding, radial acceleration about the track in the tissues is not as marked and therefore there is less pulping at a distance from the track.

Among the low velocity penetrating wounds of the head are perforation by knife blade car door handle golf stick, umbrella end, brick, and varione other everyday objects The management of

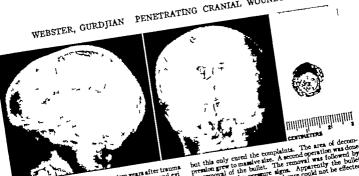

Fig. 7. Bullet would of head seen two years after traums for bedsaches. Examination showed cheked discs and evi denote of motor livitation in left lower limb Supported cyst amout butter was disproved by air encephanograms. The first operation consisted of decompression and tapping for a possible cyst. Decompression was thought sufficient

such wounds deserves only a passing comment Aside from the possibility of injury to the blood vessels with consequent formation of mass lessons (81) low velocity penetrating wounds of the brain do well under conservative management by careful debridement of the wound of entrance and inspection of the skull and durn. If the inagment is still in the cranni cavity it is removed. Obvi ously pulped and necrotic ussue is sucked away No extensive track debridement is necessary but with lacerations of the brain the possibility of intracerebral hemorrhage should be kept in mind The removal of large clots from the area of wounding may be lifesaving In Figure 6 are seen the x ray films of the skull of an adolescent youth A broken-off fan blade is seen in the right frontopanetal region near the midline. Although con sclous on admission within 2 hours he became semiconscious and before operation he was coma tose Following the removal of the fan blade a 22 gm. intracerebral clot was evacuated from the missile track. The patient awakened within a few minutes while on the operating table Usually low innuites while on the operating name on the low velocity penetrating wounds, if see in the low velocity penetrating to the careful observation for acute stage, do well, but careful observation for complications are complete and for homin absence to complete the careful observation of the complete the careful observation of the careful observation observation of the careful observation observation observation of the careful observation observa complicating meningitis and/or brain abscess is recommended. In the cases in which a patient is seen several months or years following a penetrat ing wound of the head with the foreign body still In the brain the fragments should be removed annce the possibility of eventual infection about the foreign body is ever present. Dretzka (56) une ioreign pody is ever present. The table (39) reports an instance of brain abscess about a broken knife blade in the left occipital lobe the

but this only cured the companies. The area of decompression grew to massive size. A second operation was done to removal of the builty. The removal was followed by the removal was a second operation. for removas or one pressure signs. Apparently the bullet summercine is the present ages. Apparently the other behaved like a brain tumor and cure could not be effected. without its removal (83)

injury having been sustained to years previously The abscess and the broken knife blade were removed and the patient recovered. There is no valid reason that easily accessible foreign bodies should not be removed even if they are asympto-

Penetrating craniocerebral wounds of civilians by bullet and low velocity missiles have been the besis for only a few articles since World War I matic. The reviews by Hanson (86 87), Pilcher (152) Walker (207) and the articles by Coleman (38), Goode (13) Gurdian and Buchstein (82) and German Hrody and Harvey (69) complete the American list. Goode (73) discusses the cases seen in the Cincinnati General Hospital Of 105 gun in the continuous of the head, 96 presented dural penetration and a mortality of 80 3 per cent resulted. All of 34 patients with perforating wounds died In 2 patients retained bullets caused no symptoms, for a 10 year period in one and an eight tients were operated upon with a mortality of 45 I een month period in the other per cent. Goode suggests exchang of the wound, of fragments of bone and of the foreign bodies if possible A fascia inta transplant is recommended for dural repair Gurdjian and Buchstein (82) reviewed cases of gunshot wounds of the head treated at the Detroit Receiving and Grace Hospitals. Of 45 patients 11 had no fracture of the skull while 34 had fracture of the skull and penetration of the dum or both Among the group with no fracture 1 had a left parietotemporal subdural hematoma Of the 34 with fracture of the skull and penetration of the dura or both 16

Fig. 8. This patient presented a cerebrospinal riboserbose associated with straingists, cortical attentions and as in location represents the straingist of conductivity of bridgement with elements of the straingist of conductivity of the straingist of careful state, which we present a few The core wound was subsequently covered with a solid thick case graft.

died in 9 hours or less and 5 deed in 26 hours or died in 9 hours or less and 5 deed in 20 hours or less. It was concluded that the state of consciousness is of prognostic significance in this class of ness is or programme argumentor in the case into three classes first, unconscious and moribund second, semiconscious and responsive to stimuli and, third, conscious. In the first group all died within a few hours after entrance into the hospital. The patients in the second group carried on long enough to develop evidences of increased intracranial pressure, hyperthermla, and hyper intracrama pressure, appearance of the pressure of the pressur puce. An initially low pulse have made belowed by a rapid; thready pulse. Five of this way in the pulse for any analysis of the animal pulse. group died in 20 hours or less after entrance 1 patient lingered on for 5 days, and the other re covered. Among 11 patients who were conscious on entrance 9 recovered and 2 dled 1 having re fused operation. These authors similarly suggest early operation for debudement removal of bone fragments pulped brain tiesue and metallic fragments if possible German, Brody and Harrey (69) review a group of compound cranlo-cerebral injuries. Of 64 patients, 9 had bullet wounds of the head, 6 died, 1 before operation. All traversing wounds terminated fatally

In the preparation of the present review no cases of dural penetration by bullets were no cases of dural penetration by bullets were not the complete for a period of a period of a great penetrational died of 3 deed in 20 years. Evident and a dural constitutional died of 3 deed in 20 years. Evident parameters of the state of the state of the proposatic important on from a to 44 days. The national died in the state of conscious temporation of the state of conscious many that it who survived from a to 4st days among the 1st who survived from a to 4st days and total debridement might have savel some lives.

In comparing military and civilian experience, civilian like from builter wounds of the head in civilian like from the first most civilian like from a pyalling. One reason for this the immediate input most civilian who survive death while in military practice compassible compassible from the first manufacture of the first military practice compassible compassible for the first military practice compassible compassible for the first military practice compassible for the first military practice.

lt appears that the proper mangement of it appears that the proper mangement of pentils and transportation of the proper mangement of the transportation of the proper mangement of the transportation of the proper operative intervention a partition of what could be accomplished with the transportation of the

agents to fight infection has undoubtedly been of careful derivations to the control of the cont

per Unless a patient with a bullet wound of the brain is in a moribund state on entrance, all effort ally brain is in a moribund state on entrance, all effort is considered by the should be made to give supportive and resultance of the statement. It is probably true that little can be accomplained for those who will diswithin a bullet true the statement of the bullet true, to remove a few hours of the injury. For some of those who ided close from the bullet true, to remove a few hours of the bullet true, the remove of careful and complete debudement cannot be completely all the sequence of the seque

377

masse to expose the dural defect. Careful debridement of the dura, brain and the track are then carried out with the aid of suction electrocautery is used for hemostasia. The use of fibrin foam or cellulose cotton with thrombin may be indicated in some cases The dural defect is repaired with fascin lata or temporal fascia. The value of whole blood transfusions during the

operation cannot be overemphasized Metallic foreign bodies in the cranual cavity should be removed whenever possible. There is no reason for leaving them in the cranial cavity if they are easily accessible Foreign bodies which have lodged in the crantal cavity for many months or years, such as broken knile blades or ice picks, should be removed An maccessible bullet which may remain asymptomatic for many months or years may eventually cause symptoms necessi

There is a difference between civilian and militating operative removal (Fig. 7) tary forms of brain abscess. Simple drainage, of a brain abscess following a gunshot wound is seldom successful Excision of the abscess, frag ments of bone, hur and other foreign material is mandatory if a good result is expected Civilian abscesses can be drained with success (40 72 167 172) There is some evidence to show that late sequelae following crillian abscesses cured by drainage are fewer and less serious than those oc curring after the abscess has been excised or al lowed to extrude (42 74) However radical attack of cavillan brain abscesses is advocated by King (112 113) Kahn (111) Vincent (201 202) Pennybacker (148) and others. Vincent taps the abscess and later excises it like a deep seated ex panding lesson In dvillan practice the location of the abscess may be important for deciding on

Excision may be more seriously considered in the silent portions of the brain but if an abscess were located immediately beneath the motor centers drainage with cure may result in less disability In an earlier article on cerebrospinal fluid rhinorrhea due to traums the present authors (83) discussed the seriousness of cases with com plicating brain abscess and meningitis. Excision of the abscess in such a case and exposure of the fistula and repair (fascial transplant if necessary) can be entertained seriously in a manner described for military cranio-orbital wounds by Webster Schneider, and Lofstrom (210) (Fig. 8) With the aid of chemotherapeutic and biologic

the type of management (dramage or excision)

agents, early careful and complete débridement becomes a well established procedure in craniocerebral bullet wounds both to minimize post traumatic infection and occasionally to save life.

Fig. 8. This patient presented a cerebrosphael rhinorrhes essociated with meningitis, cortical ulceration, and an infected wound. Management consisted of secondary dibeldement with closure of the dura by means of a temporary graft of fascia lata, which was removed later. The open wound was subsequently covered with split thick ness graft.

died in 9 hours or less and 5 died in 26 hours or less. It was concluded that the state of consciousness is of proguestic significance in this class of patient. These authors group their cases into three classes first, unconscious and moribund second, semiconscious and responsive to stimuli, and third, conscious. In the first group all died within a few hours after entrance into the hospital. The patients in the second group carried on long enough to develop evidences of increased intracrantal pressure, hyperthermia, and hyper pnes. An initially low pulse rate was usually followed by a rapid thready pulse. Five of this group died in 26 hours or less after entrance, 1 patient lingered on for 5 days, and the other re covered. Among 11 patients who were conscious on entrance o recovered and a died I having refused operation. These authors similarly suggest early operation for debridement-removal of bone fragments, pulped brain tissue, and metallic fragments if possible. German, Brody and Harvey (69) review a group of compound craniocerebral injuries. Of 64 patients, 9 had bullet wounds of the head 6 died, 1 before operation All traversing wounds terminated fatally

In the preparation of the present review roccases of dural penetration by bullets were reviewed from the records of the Receiving and Grace Hospitals for a period of 20 years. Eighty three patients deed 63 defed in less tian is boun, 9 additional died in 48 hours or less, and the reaining 11 carried on from 2 to 42 days. The prognostic importance of the state of consciounces was again evident. It seems fair to state that among the 11 who survived from 2 to 42 days, timely and total débridement might have saved some lives.

In companing military and civilian experiences, the mortality from bullet wounds of the head in civilian life seems appailing. One reason for this high mortality is that most civilians who survive the immediate injury reach a longituple before death, while in military practice comparable cases are seldom seen at an executation longitude because of the lack of equally rapid transportation

It appears that the proper management of penetrating wounds of the brain by high velocity missiles was well worked out at the conclusion of the last war on theoretical grounds. During World War II, with the help of better trained personnel and the necessary instruments for proper operative intervention a practical demon stration of what could be accomplished was given. A thorough debridement, removal of all foreign organic matter and removal of all pulped brain tissue was accomplished in many instances with no sequelae of infection weeks or months later. The use of chemotherapeutic or biologic agents to fight infection has undoubtedly been of inestimable value but they alone and without careful débridement would have falled. In the following few paragraphs the management of civilian craniocerebral bullet wounds is considered, as well as the lessons learned from war wounds which may be applicable to civilian nnctice.

Unless a patient with a bullet wound of the brain is in a morbund state on entrance, all effort should be made to give supportive and residualive treatment. It is probebly true that blut can be accomplished for those who will die within a few hours of the injury. For some of those who resuctiate, operative management to remove blood dots from the bullet track with careful dibridement may be lifeaving. The importance of careful and complete debridement cannot be overemphasized for upon it depends the prevention of late sequelae in the form of meningities and/or brain abscess. Long curved inclinea may be used to expose the skull defect, and the bone may be roughered away are there has removed en

masse to expose the dural defect. Careful debridement of the dura, brain and the track are then carried out with the aid of suction electrocautery is used for hemostasis. The use of fibrin foam or cellulose cotton with thrombin may be indicated in some cases. The dural defect is repaired with fascia lata or temporal fascia. The value of whole blood transfusions during the operation cannot be overemphasized

Metallic foreign bodies in the cranial cavity should be removed whenever possible. There is no reason for leaving them in the cranial cavity if they are easily accessible. Foreign bodies which have lodged in the cranial cavity for many months or years, such as broken knife blades or ice picks, should be removed. An maccessible bullet which may remain asymptomatic for many months or years may eventually cause symptoms necessi

tating operative removal (Fig 7)

There is a difference between civilian and military forms of brain abscess. Simple drainage of a brain abscess following a gunshot wound is seldom successful. Excusion of the abscess frag ments of bone, hair, and other foreign material is mandatory if a good result is expected Civilian abscesses can be drained with success (40 72 167 172) There is some evidence to show that late sequelae following civilian abscesses cured by drainage are fewer and less serious than those occurring after the abscess has been excised or allowed to extrude (42 74) However radical attack of civilian brain abscesses is advocated by King (112 113) Kahn (111) Vincent (201 202) Pennybacker (148) and others. Vincent taps the abscess and later excises it like a deep seated expanding leaon. In civilian practice the location of the abscess may be important for deciding on the type of management (drainage or excision) Excusion may be more semously considered in the silent portions of the brain, but if an abscess were located immediately beneath the motor centers, dramage with cure may result in less disability

In an earlier article on cerebrospinal fluid rhinorrhea due to trauma the present authors (83) discussed the seriousness of cases with complicating brain abscess and meningitis Excision of the abscess in such a case, and exposure of the fistula and repair (fascial transplant if necessary) can be entertained seriously in a manner de scribed for military cranio-orbital wounds by Webster Schneider and Loistrom (210) (Fig 8)

With the aid of chemotherapeutic and biologic agents early careful, and complete debridement becomes a well established procedure in cramocerebral bullet wounds both to minimize post traumatic infection and occasionally to save life.

# ABSTRACTS OF CURRENT LITERATURE

# SURGERY OF THE HEAD AND NECK

### HEAD

Lubschitz, K. Adamantinomas of the Jaw with Reference Especially to Their Treatment 4.63 Radiol., Stockh. 1945 26 441

Adamantinomas are epithelial tumors which occur chiefly in bones and especially in the laws the lower law being affected more frequently than the upper Though the tumor is benign histologically it often proves clinically malignant, because of its particular features. It may recur despite repeated surgical intervention and may be responsible for a fatal

In the jaw at least adamantinomas occur a little more frequently in women than in men Most often the tumor develops between the ages of 20 and 40 years but it has been found as early as at birth and as late as at the 76th year of age. Its growth is slow and in the beginning it does not give rise to symptoms but as it increases in size it causes the bone in which it is situated to expand This first interferes with chewing later, deglutition and respiration may become difficult there may be pain and hemor rhages, perhaps spontaneous fructure. Owing to the slow growth however it may often be several years before the symptoms become so marked that the patient finds it necessary to consult a physician.

Morphologically, two forms of adamantinoma may be distinguished solid and polycystic. The former is the rarest. The etiological connection be tween the adamantinoma and the enamel organ is shown by the similarity of the microscopic structure

Operative removal of the tumor has been practiced ever since its nature was recognized enucleation cauterization, and resection of the por tion of bone containing it are mentioned in the

The author gives an account of 11 cases of the disease. The patients were treated at the Radium literature Center in Copenhagen, during the period from 1932 to 1943 Seven of the patients were males and 4 were females. In 7 patients the tumor was situated in the upper jaw and in 4 the lower jaw Eight of the tumors were cystic, 3 were solid the latter oc curred in the 3 youngest of the patients

The roentgen examination is an important aid in the diagnosis, which especially in tumors of the lower naw may often be established with consider able certainty on the basis of the roentgenologic picture. In the film the tumor appears as a well deined rarefaction or as several more or less confluent rerefactions, which often cause expansion of the bone. In the upper law the picture is less charac terratic, the tumor often (at least in the beginning) shows itself only by a blurring of the maxillary sinus

sometimes by an expansion of the latter and only after some time do also signs of destruction of the bone appear Only the histological examination, after biopsy or operation, makes the diagnosis absolutely

The author discusses the therapeutic results and stresses the clinical malignancy of the tumors, as contrasted with their histological benignity She points out that the clinically malignant character of adamantinomas makes complete primary removal important—in the case of solid adamantinomas by enucleation, and in the case of cystic adamanti nomas by resection. Roentgen treatment can only be used as a palliative measure JOSEPH K. NARAT M.D.

### EYE

Kekcheer K. K.: Methods of Accelerating Dark Adaptation and Improving Night Vision Wer

The author discusses methods of accelerating the dark adaptation of the eye with the view of im proving night vision. Methods include (1) regu lating the adaptation before passing into darkness (2) wearing goggles with colored lenses (3) exposing the eyes to white light (4) exposing the eyes to red light and (5) employing gustatory and olfactory simuli. These methods are not equally valuable. The choice of method used depends on the circum stances at the time of adaptation. HUNTER H. ROMADIE, M.D.

Hardy L. H., Rand G., and Rittler M C.: Tests for the Detection and Analysis of Color Blind tor the Detection and Analysis of Color Blind ness) An Evaluation of the Ishihara Test Arck.

In this article the author and his coworkers evaluate the Ishihara test. They believe that the test is a gross one for defective red and green vision but falls to classify the type of color vision. For this reason it cannot be used to give a satisfactory evalu ation no matter how carefully it is administered HUNTER H. ROMAINE, M.D.

Shapland, C. D : Two Cases Showing Unusual Intraocular Foreign Bodies. Proc. R. Soc. M. Lond., 1945 38 663.

In this article the author describes 2 unusual cases of intraocular foreign bodies one of which showed the possibility of the retention of nonmagnetic metallic fragments in the eye for five years with no evidence of inflammatory complications and no evi dence of degeneration from chemical action. In the second case the eye retained multiple particles of stone without evidence of pyogenic infection. The absence of this infection apparently is due to sterl lization of the particles by the heat resulting from the explosion at the time of the accident. HUNTER H. ROMAINE, M.D.

Struble, G C. and Kreit, A. J : War Injuries of the Eyes and Visiral Pathways. War Med., Chic.,

The authors discuss the factors leading to eye injuries in warfare and the type of injuries sustained and illustrate the various forms encountered. They and musicate the various joints theoretical mannote that serious lealons of the eyes, including mac ular disturbances, may be caused by blast concustion alone, without any penetrating injury Penetration of the orbit by minute shrapnel fragments which do not penetrate the goods may also cause exhibit do not penetrate the goods may also cause serious intraocular damage. No cases of ocular injury following severe war traumas of the mandible were encountered and the authors believe it possible that the temporomandibular joint may absorb some of the concussion. Severe unlateral facial wounds have resulted in damage to the eye of the same skie,

All persons who have been exposed to a severe but never the opposite eye. blast or who have incurred war wounds about the head should have a thorough eye eramination, esnean anough have a thorough type transmission, especially as to fundl and visual fields. There should also be a complete roentgenological examination of the skull, the facial bones, both orbits and the optic forming for evidence of fracture or foreign body WILLIAM A. MARN M.D.

Devoe, A. G | Surgery of the Anophthalmic Orbit. Am. J Ophik., 1945, 18 1346.

An opportunity to see a large number of anophthaimic sockets in military service has resulted in an analysis of some of the difficulties encountered in the use of a properly fitting prosthesis. The commonest single cosmetic blemish seems to be the retraction or sinking of the upper lid with loss of the normal lid crease. This may be due to a change in the normal direction of pull of the levator to loss of orbital theme, to atrophy of the orbital fat, to overlapping of the muscles over an implant with the levator pulled down by the superior rectus, or to use of a large implant, as has been suggested by various authors. It is difficult to overcome this by changing the shape or size of the artificial eye. Attempts to overcome this difficulty have been attempted by (a) severing the attachments of the superior rectus and the levator at the time of enucleation, (b) delayed implantation of a glass sphere, (c) implanta tion of cartilage on the floor of the orbit, and (d)

The results of the first method are inconclusive. dermal graft to the upper lid. As to the second method, it is often difficult to find Tenon a capsule for delayed implantation, especially i enon a capsuse nos ucasyco unpastrazion, capecani, under general anesthesia, and in general this method was found unsatisfactory. If there is a de-method was found unsatisfactory. pression of the floor of the orbit, carrilage may be The author has had implanted subperiosteally

good success with dermal grafts in these cases good success with dermai grants in the high and Thick akin from the back is implanted high and superficially beneath the skin of the upper lid, using

The next most common defect is one which usually occurs after an artificial eye has been worn for many two layers. years there is difficulty in retention of the eye doe to a relaxation of the orbicularia. An operation simflar to Wheeler's method for shortening the orbicshad to window a memory for secretaring one whose larls in spastic entropion may be performed, and the author used this method in 4 cases, with success in 2 In the s cases in which this operation was not see cessful, the defect was corrected by the use of a mucous membrane graft after dissection of the con

functival surface below the tarsus. The author believes that the use of skin grafts in the socket should be avoided because of the resulting discharge and odor especially where both skin and

The surgical procedures described should be used mucous membrane are present. only after all attempts to correct the defect with a properly fitting eye have failed

WILLIAM A. MARR M.D.

Record A. B.: The Iridencieles Operation for Glaucoma. Arca. Ophila., Chic., 1945: 34 350.

Of 61 eyes upon which the author performed an iridencies operation for placeoms, the disease was arrested in 5s and in 9 the results were considered unsatisfactory Failure in a cases was believed to be due to a poorly placed incusion in the remaining? the patients had undergone previous trephine opera tions or had shown used pathology and were therefore unsultable for this method of surgery

The author emphasizes the importance of making the kerstome inclaion in the sciers a mm. behind the limbus, and producing an iridodislysis, feaving both iris pillars incarcerated, which suggests some variance in technique from that which is usually enployed. He prefers to inche the conjunctive with the keratome 10 mm from the limbus dragging it down to the point of incision in the sclera rather than to make a clean dissection down to the sclera before

It is emphasized as has been brought out by inserting the instrument. others, that this operation is most useful in cases in which the intracular tension is not too high-pref erably under so mm. Hg. (Schlotz) It is not indicated in cases of long standing, in aphacia, or in cases in which previous operations for glaucoma have

The author has encountered no serious complica tions with the operation, and has thus far observed been unsuccessful. no instance of sympathetic ophthalmia following it.

Muldoon, W. E.; Restoration of Patency of the Nasotacrimal Duct. Am. J. Ophib. 1945, 38 1340.

The author has placed vitallium tubes into the nasolarrimal duct in 4 cases of stenoris of the duct with a fairly good end-result in at least 3 of the cases. The principal advantage of vitalihim is its lack of tissue reaction the metal may be left in position permanently, and for this reason it has had widespread use, especially in orthopedic surgery Doberty first reported its use in ophthalmology as

The author exposed the lacrimal sac by a 13 mm an orbital implant. curved skin incision and through a small incision in the sac curetted the nasolacrimal duct and then placed the vitallium tube into the bony canal with the shoulder resting on the ram of the canal The in culon in the sac was closed with ooo plain catgut and the skin and subcutaneous tissues were su tured in the usual manner A pressure bandage was applied for several days, and the canal irrigated through the upper or lower punctum one or two

It was found that in most cases a tube 3 mm in weeks later diameter could be inserted without difficulty Because the metal is extremely hard it must be cast and therefore the walls cannot be less than o 5 mm in diameter This inside diameter of 2 mm seems to be adequate for drainage. The length of the tube is 18 mm., which the author believes to be desirable. In one case, a tube 2 mm in diameter was used leaving a lumen of only 1 mm which does not seem

The author points out the advantages of this proto be adequate cedure over a dacryocystorhinostomy and the im provement reported in his cases would seem to ray films of justify further use of this method the tube in position are reproduced

WILLIAM A MARR M.D.

### Reis, J Lat A Corneal Graft Operation for Recurrent Pterygium Bril. J Ophik 1945 29 637

The author describes a corneal graft which he uses in association with pteryglum operations in order to prevent the postoperative cleatrical opecity with subsequent vascularization which occurs following the general surgical procedure. He believes that the optical and coametic results are better and that there is less likelihood of recurrence. The technique is plainly described

### Krause, A. C.: Congenital Cataracts following Ru bells in Pregnancy Ann Surg 1945, 122 1049-

The author reports 5 cases of congenital cataract which followed rubella in pregnancy, and discusses the preventive, conservative and radical treatment

In Australia an unusual number of congenital of fetal rubella. nuclear bilateral cataracts appeared as a mild epidemic in infants. Damage to the lens evidently occurred during the first lew months of pregnancy in mothers who acquired German measles during the second or third month of pregnancy The cataracts were associated with many other congenital defects. Mental retardation occurred in 4 infants congenital deaf mutism in II and heart lesions in 21

In a series of 124 cases reported in the literature in which pregnant women were diagnosed as having rubella, 96 infants had cataracts.

In view of the seriousness of the complications therapeutic abortion should be considered if the disease has occurred in the first 4 months of preg Treatment with convelescent serum should also be considered Krause stresses the importance of early surgical treatment of the cataract before the ability to develop firstion is lost this would be before the age of 3 months JOSHUA ZUCKERMAN M.D.

### Scholz, R. O.: Epirascular Choroldal Plament Streaks, Their Pathology and Possible Prog. nostic Significance Bull Johns Hopkins Hosp.,

The author describes 5 cases of epivascular choroidal pigment streaks, rosary streaks of Siegrist, and reviews the literature on this subject

The majority of the patients considered had by pertensive cardiovascular disease and in some of them renst involvement was indicated It was possible to follow up the study in I Instance with autopsy findings. Anatomical reconstruction indi cates that the ophthalmoscopic picture is produced by proliferation of the epithelium over partially sclerosed choroidal arteries. It is suggested that the presence of these streaks is of prognostic value, and in the majority of cases a poor prognosis is indicated

### Rodin F H: Hypertensive Retinopathy Assodated with Adrenal Medulary Tumor (Pheo-chromocytoma): A New Clinical Entity Arch.

Ophik., Chic., 1945 34 402

Pheochromocytoms is a rare form of chromaffin tumor arising from the embryonic sympathetic nervous system. The adrenal medulla is composed of chromaffin cell tissue hyperplasts of which is con sidered the rarest form of adrenal tumor. It is char actenzed by a train of hypertensive changes, in cluding definite ocular changes Epinephrine or an epinephrinelike pressor substance is contained in the cells of the tumor This substance freed in the bloodstream causes vasoconstriction elevation of the blood pressure and stimulation of the sympa thetic nervous system. In the eye there is a typical In a case reported by the author there was an ex hypertensive retinopathy

tensive retinopathy of a hypertensive type with hemorrhage and exudates. These findings disaphemorrhage and exudates. These findings disappeared following removal of the tumor Serial fun dus photographs illustrate the findings in the eyes prior to and after removal of the pheochromocytoma The author believes that this is a new clinical

entity which should be called a hypertensive reti nopathy associated with adrenal tumor WILLIAM A. MARK M.D.

Bedell A. J : Clinical Differentiation of Emboli in the Ratinal Arteries from Endarteritis. Arch. Ophi Chic, 1945 34 311

The author describes a means of differentiating emboli in the retinal arterial system from endar teritis. In cases of embolism the arteries become mere threads and are greatly reduced in size, whereas in endarteritis the arteries are not as small as those found in embolism. In addition, in the latter case tound in emission. In airmoon, in the battle care always white plaques along the walls of the vessel. In embolism the retinal edema is limited to an oval area which includes the disc and macula an over more much medical the edema usually involves the entire visible fundus. In cases of endarteritis there is always some evidence of pre-existing arterial disis aways some evenence of pre-caseing access usof vessel caliber indentation of the veins and exudates, hemorrhages, or other signs of arterioscie-HUNTER H. ROMADIE, M.D. rosis and hypertension.

Henry G A.1 Blast Injuries of the Ear Larysts

In this article are presented the findings and impressions gathered from \$92 men sustaining blast ear Injuries. These cases were seen during the Battle of Europe at a large hospital part time under canvas and later in buildings. They came chiefly from in

Tinnitus was the most common and by far the fantry and armored units. most persistent of the symptoms It occurred in one ear in 124 patients and in both ears in 48. Usually it lasted for from only a few days to a month, but in a large minority it persisted continuously for from a few months to a year Vertigo was not a prominent symptom. A few of the men stated that they found blood in their ears shortly after the blast many more found a slight discharge a day or two later. On cramination however it was surprising to find how few had evidence of blood in the canal or middle car

Headache of the usual frontal parietal, or occipital variety was occasionally a complaint, but it did not occur more frequently in this group than in a similar number of soldlers without blast ear injuries one hundred and fifty two patients suffered per foration of the car drum, 114 had a single perforation of 1 cardrum 13 a double perforation of 1 drum and so had a single perforation in both tympanic mem branes. Hemorrhagic areas of the drum were present oranes. In 36 cases. External of the was present in rear canal

20 times, and in both ears 22 times. In the beginning nearly all cases had a combin ation of conductive and perceptive deafness. The greatest hearing improvement occurred in the first 10 days most of this in the first 4 days. The majority of cases continued to show improvement in perceptive hearing a few showed gradual deterioration.

It seemed likely to the author that about twothirds of the men would recover completely Others would unquestionably be inconvenienced by loss of womes unquestrousers to monovemental by was unbearing in one car and a smaller group would require the help of a hearing ski Unfortunately a few will the help or a negating any unnorthing that they will require have so much loss of hearing that they will require NOAE D FARRICANT M.D. instruction in lip reading

Struble, G. C.: Penkcillin Therapy in the Practice of Otologympology Arch. Older Chic., 1945 41

The parenteral methods used for the administra tion of penicillin consisted of intravenous drip for the first 24 or 48 hours in the most severe infections, followed by intramuscular infections every 3 hours.

Local methods of application consisted of the in-stillation of isotonic sodium chloride solution contains aumation on personse assignmentation seement containing a 500 units of penicillin per I C.c. into the sinuse ing 2 300 units to perform per and the paranase ears, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and mastold cavities the filling of the paranase cars, and the paran almoses with 1/2 per cent of ephedrin sulfate in isanusca with 72 per tent or containing so units of penicillin per cubic centimeter, and the durting of

postoperative mastoid wounds with 100,000 units of

The following opinions were expressed, supported by illustrative cases. Parenteral penicillin therapy has a favorable effect in acute simuits but is not effective after acute and chronic empyema is present. Local therapy shows great promise in the emprema of sinuses. Penicillin therapy is effective in early stages of otitis media, but must be given in adequate

### NOSE AND SINUSES

Lumsden R. B.; War Wounds and Injuries In volving the Paranasal Sinuses. Edinburgh M J.,

Twenty cases of wounds or injuries involving the In 9 of these the frontal or frontoethmoidal region paranasal air sinuses are recorded was involved while involvement of the maxillary or

marilloethmoidal region occurred in 11 cases. The late operative procedures are described and JOHN F DELFH, M.D. technical points are discussed

### MOUTH

Parker D B.: Observations on the Definitive Treat ment of Maxillofacial Injuries. J Oral Surg

In examining and reviewing a large number of naxillofaccal gunshot injuries or injuries from conact with high explosive missiles in the military hospitals designated as plastic marillofacial centers one recognizes certain definite facts. The first observa tion is in great contrast to the observation of World War I in that the incidence of infection of the soft tissues and bone is much lower Two or three months after injury we find comparatively few cases of osteonyclitis or necrosis involving the bones of the face and jaws. This is unquestionably the face and jaws. The is unquestionably the state of early intelligent treatment in the forward treatment of the state The training of medical and dental officers in mavillofacial surgery and the assignment of these officers to teams working with the auxiliary surgical groups have certainly borne fruit in the better con dition of the wounds when these patients have been evacuated to the United States for intermediate or definitive treatment The second observation is that there has been a much more intelligent effort to

stabilize the bones of the face and jaws in a more nearly normal, anatomic relationship alded in avoiding the deformities resulting from collapse of the bony supporting structures of the face often difficult to overcome in the definitive Wiring techniques have been accepted as an aid in primary treatment in the overseas treatment

The medical officer has learned that the dentist is essential to the ultimate treatment of the maxillotheaters facial injury just as the dentist realises that the plastic surgeon is essential to completion of many of the oral operations and the cases as a whole Mutual understanding as to the part that each should play and a knowledge of the ultimate requirements in function and appearance, have made the plastic maxillofacial services function to the ultimate ad

When there is a loss of bone in the mandible an vantage of the patient. adequate soft tissue bed in which a bone graft will eventually be placed is essential An attempt to insert a bone graft in tense adherent cicatricial ussue will often result in failure. Such tissue should be replaced by tissue having a good circulatory bed and loose enough to accommodate a graft without pres sure sufficient to alter its contour Bony support sufficient to withstand masticatory pressure or to aid in the retention of a prostitute appliance is desirable for much of the hat surface plastic repair of the face is complete Bone grafts in areas commun cating with the mouth or in which residual infection persists (in the bed or adjoining lost bone) are of course doomed to failure although, with penicillin therapy, some of the implanted bone cells may

One of the most difficult problems attending the definitive treatment of maxillofacial injuries caused eventually survive. by penetrating missiles is the trismus resulting from the wounds adjacent to the coronoid sysomatic temporal area. The marked destruction of the tem poral and massecter muscles as well as of the buc chator muscle, results in a dense fibrosis in this area, which either limits or obliterates altogether the masticatory function of the mandible. Attention should be given both to preventing the maximum amount of fibrosis and to correcting functional dis

Another problem in the definitive treatment of maxillofacial injuries is that of adhesion of the buccal nucous membrane to the alveolar ridge of the mandible or of the maxilla, which obliterates par tially or entirely the vestibule of the mouth Such a deformity limits the motion of the lips or of the buccal muscles which results in limited motion of the facial muscles of expression. It also limits the abilityof a patient to wear a prosthetic appliance to assist or a particular to wear a prostucture appropriate to assist in functional mastication, or for cosmetic use, to improve the contour of the face. Such conditions can be treated only by deep incisions through the adherent clearry and the interposition of a split graft over a stent mold held rigidly in position LOUIS T HYAR M D

Cook, T J Royster H. P and Kirby C. K.: The Treatment of Gunshot Fractures of the Man dible. J Orel Surg. 1945, 3 320

Certain essential steps should be followed in the treatment of gnushot fractures of the mandible Control of hemorrhage catablishment of an ade quate airway temporary immobilization of the iractured bone, and treatment of shock are to be considered first. This is followed by minimal primary encision, without suture except when conditions are knowable for primary cleaner, and early immobilization of the fractured bone. Secondary minimal encision and débridement are done from 5 to 10 days after the injury secomposited or followed by delayed primary cleaner of the skin wound The authors recommend treatment of cottemyellits by early radical operation. Loys T Brass, M.D.

McNeely R. G Dr Adenolymphoma of the Sai ivary Giands. Caned. M Azr J 1945, 54 124.

Five cases of adenolymphoma of the parotid gland are reported. This type of tumor is infrequent only s cases having been found among 125 salivary sland tumors seen in the Toronto General Hospital path ological laboratory in a 10 year period. Only 2 cases of malignancy have been reported in the literature. The tumor becomes apparent as a slow growing mass near the angle of the lower jaw usually in the fifth, sixth, and seventh decade. Subjective symptoms are absent and the growth is encapsulated and easily removed. It is composed of tall, doubly placed acidophihe cells which line the ducts and glandlike arrangements into which may project papillae and which may be dilated to form cystic spaces. The epithelial atructures are supported by a lymphoid stroms with active germinal centers.

The generic of the tumor is discussed and reasons advanced in favor of the hypothesis that it arises from salivary duct epithelium. The lymphoid tissue apparently serves as a supporting atroma and appears to participate in the menphatic process.

### NECK

McArthur J W., Rawson, R. W., and Means, J H.: Idiosyncratic Febrile Reactions to Thiouracti, Clinical Characteristics and Possible Pharms cologic Significance. Ams. Int. 11, 1945 3 915

Thiouracil was employed in the preoperative preparation of rop patients suffering from thyrotoclosis. Tork reactions (applying the term in the most in chaive sense) occurred in 15 instances. In 5 cases lever was the most completions feature of the reaction. The case reports of 3 patients who developed fever are presented, with speculations as to the fundamental alguideance of the following cases:

The sudden onset of fever after a relatively constant latent period of ro days, the arphoire immediate reaction upon readministration of the drug and the character of the accompanying symptoms assesset that thioursell reactions are manifestations of the true drug idiosyncracy. A review of the lit erature on the nature of thioursell reactions revealed the fact that attention has been focused on factors which may predupose an individual to develop an idiosyncratic reaction, while the precise chemical factors which render an agent capable of inducing hypersensitiveness have been largely neelected. It is Dointed out that the sensitizing especity of a drex depends upon chemical structure and that hyper sensitivity may be developed to the molecule as a whole or to certain radicals of the molecule. Propenanty to induce idiosyncratic reactions is stress presumptive evidence of a drug's capacity to become bound to protein. It is suggested that capacity to bind proteins is the common chemical factor which is responsible for the anaphylacticlike complications of chemotherapy as well as the therapeutic effect. The prevention of the rold hormone formation by the sulfonamides and thiouress may prove to be due to an enzyme blockade mechaniam.

Tons L. Lincount, M.D.

Kenting, F. R., and Cook, E. N: Recognition of Primary Hyperparathyroidism. J. Am. II Am., 1945, 129, 994.

Clinical hyperparathyroidinm may be divided into three groups, in accordance with the crient of the skeletal involvement. Group 1 comprises the case with the classic picture of oreight forces cyrtical generalisats, group 2 consists of cases with stypical demineralization of the skeleton, and group 3 includes the cases which showed no skeletal involvement but demonstrated renal calcult. Disease of the bone was demonstrated renal calcult. Disease of the bone was demonstrated renal calcult. Disease of the source of the cases. However renal calcult and calcifection were found in pa per cent of the cases. Classic bone this case seemed to be slightly more frequent in women than in men, whereas renal disease was more fre

quent in men. Symptoms of hyperparathyroldism were divisible into three groups in accordance with the chemical changes in the blood and urine, or the degree of in-volvement of the kidneys or of the skeletal system. Chemical changes in the blood were manifested by an increase of calcium and a decrease of inorganic phosphorus. As a result the symptoms were muscular atony weakness, fatigue and constipation, all of which could be correlated with the degree of hypercalcemia. Polyuria was present in 46 per cent of the cases and was regarded as being due to the excessive excretion of calcium and phosphorus. The latter also provided the basis for nephrocalcinosis. Hyperparathyroidism was suspected in any patient having renal calculi of calcium. Laboratory diag noxis was made on the basis of increased calcium and decreased phosphorus in the serum with a loss of calcium in the urine. Repeated blood determina tions were necessary since the elevation of calcium was slight. Thus, in 12 of the 24 cases of hyperpara thyroldism the blood calcium averaged less than 12 5 mgm. per cent. Ionic calcium was found to be specifically affected by parathyroid disease while the organic calcium proteinate was not so influenced With multiple myeloma or sarcoidosis there was a secondary hypercalcemia mainly in the organic fraction of the blood which accompanied a hyper proteinemia. When the value of serum calcium was equivocal, a low level of inorganic phosphorus, below 3 5 mgm per cent, served as a good diagnostic due. Elevation of the alkaline phosphatase was useful as an indication only of bone disease but not necessarily of hyperparathyroidism. Under properly controlled dietetic conditions a strongly positive Sulkowitch test for calcinuria was supportive of the diagnosis of hyperparathyroidism. With the Bauer and Aub diet normal persons excreted less than 100 mgm, of calcium whereas hyperparathyroid patients lost between 125 and 200 mgm per day. In groups I and a demineralization of the skeleton was manifested by pathological fractures multiple bone cysts, and miliary osteoporosis of the skull Dental roent genograms were significant when in conjunction with other bone changes disappearance of the lamina dura of the teeth was found. Examination of renal calculi caused by hyperparathyroidism showed a predominance of calcium oxalate.

demonstrated at operation In no case was a diffuse adenomatics of all parathypoid this use found. None of the adenomas in this series was in the mediastinum and none was considered malignant. After operative removal, the blood calcium and inorganic phosphorus returned to normal the former within two days and the latter more slowly. In go per cent of the patients tettany ranging from mild to severe, developed postoperatively. Severe tetany seemed to occur most frequently in those cases which exhibited extensive onseous change and high levels of alkaline phosphatase. Mild tetany was accounted for on the basin of a reverse shift in the calcium and

In all of the 24 cases a parathyroid adenoma was

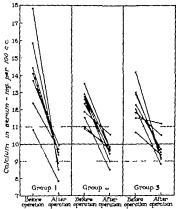

Fig 1 The changes in the average level of calcium in serum before and after removal of a parathyroid tumor. Each point represents the average of numerous determinations made, in most instances, over a period of several weeks. In 1 case in group 1 no significant change in serum calcium occurred following the operation. The level of inorganic phosphorus and the exerction of calcium were also unchanged, and this has been assumed to indicate that a second tumor is probably present.

phosphorus which created a temporary period of hypoparathyroidism B G P Shartsorr M.D

### SURGERY OF THE NERVOUS SYSTEM

#### PERIPHERAL NERVES

Sunderland, S.: Traumatic Injuries of Peripheral Nerves; An Analysis of the Incidence in 361 Consecutive Cases of Peripheral Nerve Injuries. Autral N Zealand J Surg. 945 15 25.

The author presents a statistical summary of sor consecutive cases of peripheral nerve injuries observed in military centers in Australia, during the period from 1941 to 1944. The data, summarized mainly in several charts give the incidence of injury according to the cause ([1] gunshot wounds of war and [s] kestons due to other causes? the location of the injury as to nerve or combinations of nerves, whether the injury was right or left-sided and whether the injury was complicated by bone injury as well. It was found that plexus injuries predom insted on the left that lesions of the ulnur nerve occurred twice as often as those of the median or radial nerves which were involved in approximately equal proportions and that in combined lexions the radial median and ulnar nerves were affected in equal proportions. In upper limb injuries single nerve lesions outnumbered combined nerve lesions 6 to 1 and upper limb injuries were three times as numerous as those in the leg Gunshot wounds of the sciatic perve were nine times as numerous as those due to other causes. In the gunshot injuries lesions of the ulnar nerve predominated also this nerve was more frequently the common factor in combined lesions than either the radial or median nerve. The commonest cause of peroneal nerve in jury was the pressure of a plaster cast.

JOHN MARTIN M.D.

Sunderland S: Blood Supply of the Sciatic Nerve and Its Popliteal Divisions in Man. Arck. New Psychiat., Chic., 1945 54 283

The author studied in considerable detail the gross and microscopic characteristics of the vascular patterns of the sciatic nerve in 40 adult human cadavers, with special attention to the gluteal region, the upper middle and distal thirds of the thigh, the poplitesi fosse, the neck of the fibule, and the upper middle and distal thirds of the lower portion of the leg. He found that the largest ar terise nervorum of the entire body were those supplying the sciatic nerve in the buttock and thirth (Fig 1) They were arterioles, and they arose from the inferior gluteal artery and the perforating anastomotic chain. Nutrient arteries of the direct type predominated, and these occurred in a T-pattern most commonly when they reached the nerva. The large nutrient vessels were found to enter the nerve directly in most cases, without a long superficial course in the upper sciatic nerve. In the popliteal fosse the largest vessels ran on or within the nerve but as the common peroneal nerve approached the

Fig. 1 Illustration of a dissection, aboving the blood supply to the sciatic error from the interior gitted artery crucial anatomosis, and, in particular, the perforation anatomotic chain. The nerve has been displaced medially to demonstrate the latter

neck of the fibula the larger intraneural vessels were found to occupy a superficial and exponed position in 58 per cent of the specimena, and a deep and protected position between nerve fasciculi in only 12 per cent.

Not only is the peroneal nerve a smaller and less will protected nerve than the thial, which might partially account for its susceptibility to pressure effects bott its also usually in the form of one make bundle so that its vessels have poor protection from outside pressure. Furthermore the peroneal nerve is poor in supporting and protective adjoose these. The thial arteriate nervorum have the added protection that they lie in crevices between several bundles of the nerve.

An excellent table is provided to show the source and number of the nutrient arteries to the sciatic nerve in man.

Jose Marrix, M.D.

Barnes, R., Bacsich, P., and Wyburn, G. M.; A. Illatological Study of a Predegenerated Nerva Autograft. Brk. J. Surg. p45, 33, 130.

For purely investigative purposes, the authors per formed an autograft in a patient with a large and irreparable injury to the ulnar nerve. Seven centimeters of the distal segment of the nerve were ex cised, and were then sutured to the freshened distal end of the proximal segment. The graft was 3 millimeters in diameter and the central segment was 6 millimeters in diameter so that contact of only about 25 per cent was obtained between the stump and the grait. Three fine linen thread sutures were passed through the sheath of the nerve to effect this contact, and the distal end of the graft was then su tured to the intermuscular septum. There was little or no scarring of the soft tissues in the new graft bed This operation was performed 613 days after the

After an interval of 168 days the wound was again opened and the graft inspected. There was onginal injury firm healing at the line of suture and at that point there was a firm fusiform swelling of the nerve The graft was firmer than at the time of insertion and it was not unduly adherent to the surrounding tissues. The graft was then stimulated with the faradic cur rent (this operation having been done under local anesthesia) but no sensory response was obtained dutal to a point I cm below the suture line. The entire graft together with 2 cm of the central stump was then removed for histological study

This autograft was found not to have undergone any central necrosis, and it had provided a pathway for new nerve fibers some of which were found to have proceeded for 20 mm beyond the suture line None of these new fibers were meduliated and the transition from meduliated to nonmeduliated char acter took place abruptly and immediately above the sature line. In the opinion of the authors this absence of medullation may have been due to ex tensive intrafasicular fibrosis which prevented nor mal maturation of the nerve fibers While the new nerve fibers in the graft were neither normal in anatomy or quantity it was of agnificance to the authors that such an old predegenerated autografi could receive nerve fibers after so long a time and that a central stump still could retain regenerative powers as long as 613 days after the onginal injury

## BRAIN AND ITS COVERINGS; CRANIAL

Murphey J P and Gellhorn E.; Multiplicity of Representation Versus Punctuste Localization the Motor Cortex; An Experimental In restigation Arch. New Psychiat Chic., 1945

This report of an obviously carefully worked out investigation indicates that there is a multiplicity of motor representation in the cerebral cortex rather than the commonly conceived restricted localization of motor function. In the words of the authors em phasis is shifted from solated cortical representation

to more inclusive cortical function. The animals employed in the study were the rabbit, cat and monkey these animals being chosen to determine whether or not results of cortical stimu

lation executed after an original concept of the authors, could be correlated with the principle of progressive encephalization. Such correlation was in fact, possible but to a limited degree, and the broad concept of multiple cortical representation was found to be maintained in this admittedly limited

The authors believe that in stimulating the cortex it should not be subjected to the weakest possible phylogenetic arc electrical currents but that the aim should be to evoke as much as possible of the total capacity for physiological response. Under such conditions of cortical stimulation they found that multiple representation of movement is widespread in the motor cortex of the rabbit, cat and monkey and that the most common type of multiple representation is that found in the large somatotopic divisions the leg arm and face. The cortical overlap of two large acm and lace. The council overlap of two saveth somatotopic subdivisions apparently decreases with progressive encephalization as the phylogenetic scale is ascended. The point is made that it is movements not muscles which are much more widely represented than the usual cortical maps would indicate Movements involving distal joints were not found biovements involving distributed than movements in-

The authors believe that this multiplicity of repvolving the proximal joints. resentation and the extent of representation of movements beyond the bounds ordinarily determined by threshold stimulation probably account for the re-tovery of function of individual parts of the body after contralateral cortical tissue has supposedly been removed

Oldberg S.: The Significance of Internal Frontal Hyperostosis and Some Related Changes of the Skeleton with Special Reference to Diabetes in the Aged (Ueber die Bedeutung der Hyperostosis frontalis interns and einiger verwandter Skelettvers eroderungen unter besonderer Beruecksightigung der Verhaeltnisse bel Altersdiabetes) U peda lak foren

During the last decades the cranial change, which for a long time has been called hyperostosis frontalis interna, has aroused an increasing interest from the clinical as well as from the pathologicoanatomical point of view Under the more comprehensive names hypophyseal cranial dysplasia metabolic crantopathy a more diffuse thickening of the calvaria is found while the afore mentioned endocrine origin of local frontal hyperostosis has been generally accepted the genesis of diffuse hyper ostosis is less clear and an association between both forms has not been proved Certain bony changes which have been assigned to the normal increase in which have been assigned to the horizon marcase in age, the so-called senile hyperostors, have been of age, the so-called senile hyperostors, have been of age, the so-called senile hyperostors, have been of the solid march discussion. The occurrence of the last mentioned change has been considered self-evident for at least 100 years but systematic investigation has not been made.

The clinical significance of the cranial changes is not clear They have been included together with adjocity and certain psychoneurological symptoms in the so-called Stewart Morel syndrome and with adjocity and virilism in the Morgagni syndrome. Some authors have emphasized that in case of local frontal hyperostosis a disorder in the carbohydrate metabolism in the diabetic sense may occur. The suggestion has been advanced that by confirming this bone formation an opportunity is afforded for diagnosing pituitiary diabetes. The circumstances, however are not cleared up and no research has been made on a larger scale.

From his x ray studies the author has tried to find out the appearance of the normal calvaria at different ages. The occurrence of the local frontal hyperostosis as well as the general thickness was observed, being directly measured on the x-ray plate at certain points. The results thus obtained were taken as a starting point and the same investigation was carried out on material consisting of selected cases of local frontal hyperostosis acromegaly hypophysesi adenoma operatively verified, and also a number of cases of senile diabetes. The author tried to clarify the so-called senile hyperostoris and the hypophyscal genesis of the diffuse thickening of the skull, and, by measuring the sagit tal diameter of the atlas tried to get a clear idea of the relationship of localised changes of the skull to more general disturbances in growth. By means of a comparison between cases with and without frontal hyperostosis and the diffuse thickening of the calvaria, respectively the author tried to find evidence for the clinical algulficance of these bone changes. Special interest was taken in the possibility of classifying the cases of so-called senile dia betes in two genetically different forms.

The result of the investigation can be summarized as follows

r Signs for the so-called scalle hyperostosis are lacking

2 Hyperostosis frontalis interna appears almost exclusively in female patients, usually first after the menopause, and increases in frequency with age. The endocrine disorder in these patients manifests fixelf furthermore in a delayed menopause.

3 The general thickness of the culvaria can be attributed directly to a disturbance in growth of hypophyseal origin. It is most pronounced with accuracyly and a little keep pronounced with chromophilic hypophyseal adenoms without acromegalic signs, whereas in the case of chromophobic adenoms the thickness is about normal, but still shows some difference.

4. Hyperostosis frontalis interns is positively correlated with a diffuse thickening of the cs parsetals and consequently with the diffuse thickening of the calvaris. Accordingly it often occurs in cases of acromegaly.

5 In cases of acromepaly as well as of local frontal hyperostosis there is furthermore, an enlargement of the sagistal diameter of the atlas. Thus, there exists an association among hyperostosis frontalis interns, the diffuse thickening of the calvaria and the enlargement of the atias, which must be considered as a general growth tendency in the akeleton. The hypophysical genesis of this bone change is discussed.

6 Hyperostosis frontalis interns and, to a certain extent, the general thickening of the calvaria are actent, the general thickening of the calvaria are in a co-ordinative relation with adiposity distincts, as the contract of the core name to be caused and hypertrichosis, there fore the term "Morgagal syndrome" seems to be inadequate. The occurrence of distincts and head-aches does not correspond to an increase in the blood pressure. In the diagnost of adiposity in its different forms the alorenamed bone changes seem to point to a hypophysical origin.

7. The occurrence of local frontal hyperesticals and to a certain degree even that of the diffuse thickening of the calvaria in women as well as in near, suggests the possibility of an extrainsalts of labetes of presents (a) a benign course not infrequently with spontaneous reasons, (b) a sight ackolot tendency and thus an inconsiderable risk of coma (c) a requirement of musilion only in a few case, exclusively those of persons who have been fill for saveral years and (d) a decrease in sensitivity to intuilio.

8 The occurrence of hyperfunction of the autricio tobe of the piculary giand expectably in women after the menopause (formerly chiefly recognized by an increased excretion of gondotropic hormone) in cludes even a growth promotive factor and probably also a dubetic one. The practical value of the forement of the forement of the picular control of the picular cont

Davison G., and Demuth, E. L.: Disturbance in Sleep Mechanism; A Clinicopathologic Study Lesions at the Corticodiencephalic Level. Ark. V in Psychia! Chic., 1945-54-341

Discrete lesions of the hypothelamus are known to cause interference with the normal physiological regulation of sleep and all the available clinical evidence indicates that lesions at the corticohence phalic level not uncommonly produce pathological sleep as well. The authors have had as patients with such pathological sleep syndromes. In all, either the cortex or the diencephalon, or both, were involved. Twenty-one patients suffered neonlastic disease, and the 4 other patients had brain abscess, encephalitis lethargica, diffuse syphilitic disease and vascular discase. A strikingly high percentage of the patients showed clearly an extensive change in the hypothele mus. This structure showed compression changes in 16 cases, actual invasion in 4 cases, and gross destruc tion in I case In a patients however the hypothalamus, though compressed did not show any change in the nerve cells. Also, in 16 patients there was in addition to the changes in the hypothalamus, compression or invasion of the basel ganglia with im plication of the strichypothalamic pathways. Inasmuch as most of the neoplasms in the series were found to have encroached upon the ventricular system a high incidence (18 patients) of increased intracranial pressure was present in this series

In a previous article the authors expressed the coming that some fibers for the control of sleep were believed to originate in the cerebral cortex especially the hypocampal, angular frontal, premotor and temporal convolutions. On the basis of the 25 case histories reviewed in the present article, they postulate that the following structures (both afterent and efferent in nature) are concerned with sleep regulation the medial forebrain bundle running be tween the ventromedial olfactory correlation areas of the cortex and the preoptic and hypothalamic areas the corticohyothalamic fibers via the forms, the inferior thalamic peduncle and a postulated hypothalamicoprtical tract. Joint Maxim M.D.

Bucy, P. C. Surgical Relief of Tremor at Rest
Ann. Surg., 1945 122 933

A case report is made of a 23 year old male with a disposis of unilateral Parkinson a syndrome on the inght side following chronic encephalitis the onset of which apparently took place at the ago of 5½ years. The patient showed marked unilateral tremor a weakness of the right lower extremity of slight degree and possibly some weakness of the right upper extremity.

Operation was performed, the central sector of the cortex of the left cerebral hemisphere was exposed up to the middle of the operative field. The cortex did not appear abnormal. All of the exposed cortex was electrically stimulated following which the posterior hall of the precentral gyrus was removed over the area which had caused movement (by stimulation) in the right upper and lower extremities. The area was resected subplially down to the bottom of the central subrass. The great rolandic vens and the communicating vens which crossed the region of extirpation were left insact.

Following operation, the patient had complete paralysis of the right upper extremity and marked weakness of the right lower extremity. There was gradual improvement in function of the right side without evidence of a return of the tremor

The last report (9 months after operation) stated that the patient was able to walk with his body upright, rather than with a hemiparetic gait. The tendon reflexes were increased on the right and al though this had been true preoperatively. There was no evidence of return of the tremor up to that time.

The area exturpated was the arm and leg' portion of area 4 Y and according to the author such exturpation can be expected to abolish tremor at rest in the contralateral upper and lower extremities. The procedure may be expected to produce some increased spasticity and increased perspiration over the right half of the body for a few days. No sensory alterations were noted. Howard A. Brows M.D.

Bailey, P: Chronic Leptomeningeal Thickening following Treatment of Meningitis with Sulfa Drugs. Ann. Surg., 1945 122 917

Four cases of meningitis are reported which were treated with sulfa drugs or penicillin. These cases demonstrated the sequelae which may occur despite the use of these drugs. In all 4 cases the acute purulent infection was controlled but despite this the condition went on to death or a serious sequel because of the fact that the drugs exert no restraining influence on the fibroblasts which proliferate rapidly in an attempt to organize the exudate.

As a result of these changes the leptomeninges become densely scarred and prevent the normal circulation of cerebrospinal fluid. There also may be construction of the blood vessels as a result of the same pathological process

The author intends to call attention to the dangers that may arise as result of these alterations in the nervous system, although early optimism may arise immediately following the administration of these drugs in the treatment of purellent meningitis.

If is not his contention that the drugs should not be used but he states that early diagnosis and intensive therapy with adequate doses before massive exudate has occurred may be of value in preventing these changes and improving the prognosis.

### SURGERY OF THE THORAX

### CHEST WALL AND BREAST

Spaiding, J. E.: Adenolipoma and Lipoma of the Breast. Gur's Hesp Rep Lond. 045 04 80.

The author reports the case of a 56 year old woman who had noted a swelling of the left breast for one year. Since the first socied the swelling the breast had stradilly enlarged Examination of the breast revealed a lump 8 cm in diameter immediately lateral to the areola. The mass was spherical, well defined and freely movable within the breast. The arillary lymph nodes were not enlarged. The breast was amputed.

The tumor mass was well defined. Microscopically the tumor consisted of fat tissue with blands of epithelium embedded in the fat. In the central part of the tumor there were large islands of epithelial tissue in which alveol, alveolar ducts and larger ducts could be distinguished.

The author considers this to be not a pure liponta but rather an adenolipoma. He described a lipomas of the breast that are in the Gordon Museum.

EARL O LATDETS, M.D.

### TRACHRA, LUNGS, AND PLEURA

Clark, D., and Gilmore, J. H.: A Study of 198 Cases with a Positive Coccidioidin Skin Test. Ass. Ist. M. 1946 24: 40.

One or more concided in intracutaneous tests were made on 379 patients, and from 125 with a positive reaction, 100 with residual roentgenographic indings in the lungs were chosen for study analysis and report. This investigation was made in the pulmonary section of an Army General Hospital serving the southwestern part of the United States in 1042

The fungus coccadioides immutis is found in and soil, and has been isolated from wild redents in central and southern California, Arisona, New Mexico and West Texas. The organism is diphasel, occurring in animal tissue as a spherule from 1-60 micra in diameter with a doubly refractile wall, and

multiplying by endosporulation.
The carliest nathological less

The earliest pathological lesion in man as surmised from suides on minals, is an infectious granuloms following the inhalation of infected dust or, more rarely entrance through a lesion in the akin. The infection is usually mild, self limited and involves the lungs and amounted mediastinal lymph nodes. Antibodies develop un the blood and the lesion disappears or fibrotis lesers a rounded or linear scar and solid immunity. Reinfection does not occur. Exceptionally an abscess may form in the lung or pleurs and heal by absorption and fibrosis, or it may break down and discharge organ isms through a bronchus which appear in the systum for months or years without canding sec ondary lesions. Rarely chiefly in individuals of the dark skinned races, the infection gains entrance to the blood stream and causes death. In survivon, granulomas appear throughout the body These tumors may be slowly absorbed or may form chronic absoraces.

The differential diagnosts included tubercolosis, residual pneumonitis fibrosis, healed septic abscess broachitis bronchiectasis Boeck's acrosid and metastatic malignancy. Attention was paid to residence in areas endemic for coccidioides akin tests for coccidioidis and tuberculum, the sediments test for coccidioidis and troberculum, the sediments test for test, specimen study of the blood for coccidioidis antibodies and roentgenographic examination of the chest.

Fifty-two patients had fever mild chills, cough, cocasional sight hemoptysis small amounts of mucoid sputnum, chest pain, and malaite. Four had akin manifestations. Evaluation of the langs could not be made without contegrograms, although plearisy plearisy with effusion, and pneumonitis secondary to couchloidal infection were sometimes

found on physical examination.

Coccidentiforny costs mimics tuberculoris however superinfection or the adult type of pulmonary tuberculosis is not characterized by hilar or me diastinal adenopathy Roeptgenographic findings may be grouped under five major types (1) with pneumonialike infiltrations (2) with tracheobronchial mediastinal or hilar adenopathy or a combina tion of both (1) discrete nodular type with a round or oval area of increased density from a or 3 to to mm in diameter occasionally calcified (4) with annular shadows having thick walls and (5) with upper lobe granular or with slightly nodular infiltrations with extension of linear markings into the hillum. As healing takes place initial pneumonia like infiltration is followed in some cases by com plete disappearance of the lesion, in others by nodular lesions, by annular lesions, or by strandlike infiltrations

Many individuals who have been in southwritten United States above a positive reaction to the cocalcioidin skin test, and some of these show room genographically persistent areas of increased density in the lungs which can be disregarded as a cause of feature Illness or disability if they are due to an inactive coccidioidal infection but they must be distinguished from tuberculosis and more narrly other potentially dangerous desases.

A long leason absent in previous chost films but present some time after an individual was on the desert is probably due to excelledolomycosis. Coccidiokim in concentrated from for skin testing in a 1 100 dilution with normal salme solution was obtained from Charles C. Smith of the Department of Public Health. Stanlord University

LYDIX JOHNSON M.D.

Camaner A : Cancer of the Lung with Initial Neurological Symptoms (Canceres de pulmón con remotogas io can consider the first statement of the first statement

Following a brief discussion of the many syn dromes due to pressure on the peripheral and central nervous systems by the growth of the metastases of pulmonary tumors the author notes that in the material at the Hospital Rawson in Buenos Aires the most common form of pulmonary tumor is silent and announces itself as a hemiplegia with a progressive subscute course with localization of the metastases at the level of the internal capsule, in the subcortical area, or in the ascending frontal or motor convolu tion. This metastatic growth then tends to invade the cortex in this area producing the Bravaus-Jacksonian type of epilepsy and later the other structures of the brain particularly the basal nuclei and ventricles and leads to an early death. There is a relatively ate appearance of evidence of intracranial pressure, the demise being due rather to the interruption of the vital nerve impulses from the central nuclei.

The article concludes with 4 typical case histories, all in males from 34 to 66 years of age. In each case the hemiplegia was on the left side, progressing rapidly to complete paralysis of the left arm and leg and in no case was any evidence of lung involvement observed until the x rays were used. By this means an original new growth was discovered at the hills of the right lung in r patient at the right vertex and base respectively, in 2 patients, and at the vertex of the left lung in the last patient. JOHN W BRESHAN M D

### Strieder J. W. and Lynch J. P. Putrid Empyema. N Excland J M 1946 234 1

A better understanding of putrid empyema to be distinguished by surgeons from pyogenic empyema will bring prompt recognition adequate treatment and long prompt accognition analysis of oo cases at the Boston City Hospital Boston Massachusetts from June, 1934 to January 1941 and of specific cases subjected to thoracic surgery between Jan usry 1938 and January 1941 demonstrates the

advantages of early radical surgery Putrid empyema a sloughing gangrenous pleur itis, is caused by anaerobic bacteria in symbosis and characterized by purulent foul, sulfurous or putrid pleural fluid and often gas. From 5 to 10 per cent of 530 cases of empyema treated at the Boston

City Hospital in 71/2 years were putrid Putrid empyema complicated lung abscess gangrenous [usospirochetal pneumonitis bronchice tass tubercalosis with secondarily infected blocked cavities which ruptured into the pleurs, pulmonary gangrene datal to obstructing carcinoma, and trauma. The acute stage of all putrid pulmonary infections is believed to be pneumonitis as distin

guished from pneumococcal pneumonia. The clinical impression on admission, was pieu monia the physical signs were those of fluid roent genograms showed consolidation even when fluid

was present. A history of foul sputum was diagnostically helpful. The patients early became toxic and delinous and showed signs of peripheral vascular collapse and the pulse was elevated out of all proportion to the temperature a feature common to all

Thoracentesis fluid with a foul odor was pathog nomonic. Direct smear revealed fusospirochetes anaerobic infections Angerobic culture of the pleural fluki demonstrated infection in which symblosis was involved and related to the antecedent disease. Vincent's angina pendental infection, and pyorthes alveolans were common in the patients from whom the organisms The infections are referred to as

fusospirochetal but anaerobic cocci are associated with them and are of equal importance Common to all anaerobes is their mability to live or multiply in an atmosphere rich in oxygen Con sequently open operation with adequate aeration and evacuation of the pus is the treatment of choice. Despite the consistency of the fluid there is prompt

If this is inadequate the pleurs is widely incised stabilization of the mediastlnum for about 10 cm A large prepared dressing is applied and the patient is quickly turned on his back. The dressing becomes saturated and serves as a tampon preventing air exchange while the large wound allows complete dramage. A quick change of dressing is made during expiration the third day Stabilization occurs from the fifth to the seventh day A gauge pack impregnated with activated sinc peroxide placed partly in the pleural cavity and partly in the wound controls odor and the wound is clean and granulating in from 5 to 7 days, when the tubes are inserted for convalescent care.

Sulfonamides and arsenicals are of no benefit, but penicilin is a valuable adjunct and effects cures in a certain percentage of cases Recovery is greatest with early operation Seventy five per cent of the patients operated upon in the first week recovered Only a patient lived when the disease had persisted to days before operation The surgical treatment generally given for postpneumonic empyema was not adquate for putrid empyens. The mortality under such conditions was 54 per cent. Three deaths among the at patients recovering from open resec tion indicate that a fatal outcome in spite of adequate surgical treatment is usually due to the primary discase. The results obtained demonstrate the bene fit of immediate surgery of the open type. The use of activated zinc peroxide packs is specifically helpful.

### SURGERY OF THE ABDOMEN

#### GASTROINTESTINAL TRACT

Fernandes, O: Roentgenological and Clinical Study of Duodenal Stants (Estudo radiológico e clinico das estases duodenais) Brasil med cirurg

1015 7 355

After presenting a short review of the embryolorical development of the duodenum, the author offers the following classification of duodenal obstruction

A. Intrinsic lesions (1) congenital partial or total absence of fixation with abnormal mobility and diverticulum, (2) acquired diverticula, bridges, ad hearons, modification of the mucosa, hypertrophy of the muscular layers ulcers tumors, and foreign hodies

B Extrinsic lesions compression by tumor and compression by a pedicle of the mesentery

C. Functional lesions spastic conditions hypo-

tonia and atony

A mobile first portion of the duodenum may form a festoon and cause obstruction. In other cases only the portion just above or immediately below Vater's papilla is abnormally mobile and in another variety of mobile duodenum only the third portion is involved. A total mobile duodenum is a rare malformation making up a part of the anomaly called common mesentery

A diverticulum may be located at the duodenojejunal junction or higher up Diverticulitis may be the sequel of duodenitis. An acquired diverticulum may form above a stenosis and results from a lack of equilibrium between the duodenal contents and

the resistance of the wall.

Bridges, bands and adhesions usually are the result of chronic adhesive peritonitis. Hereditary syphilis tuberculosis, cholchthiasis, and other con

ditions may produce an inflammatory periduoden itis Similar processes may follow more distant in fectious conditions located in the pelvis or around the appendix.

Intensive duodenitis may spread to the submu cosa and cause a hypotonus accompanied by a diminished peristalsis which leads to stars. Hyper trophy of the valvulae consiventes may also cause stasis Hypertrophy of the muscular layer may lead to the formation of a veritable sphincter

Ulcers may be caused by or provoke the occur rence of stasis because of adhesions and cicatricial stenosis Irritation of the mucosa by violent peri staltic and antiperistaltic motions and tranma of the epithelium in the presence of stasis may cause the formation of an ulcer Among benign tumors causing stasis the following may be mentioned adenoma fibroma lipoma, myoma, and hemangioma Such tumors may be sessile or pedunculated Malinnant tumors such as carcinoma, fusocellular sarcoma, myxosarcoma, and melanosarcoma are rare in this condition.

As to foreign bodies gallstones are the most fre quent.

A ptosis of the anterior branch of the vascular mesenteric pedicle may cause a pinching of the third portion of the duodenum. Two arteries may com press the anterior aspect of the duodenum, namely the superior mesenteric and the middle colic ar teries.

A chronic duodenal stasts is characterized by the following signs a rise of nonprotein nitrogen in the blood an increase of the alkaline reserve a consider able fall of the blood chlorides an intensified nitrogen excretion in the urme, a dimunition of chlorides in the urme and hyperpolypeptidemia.

Golden, R., and Ducharma, P : The Clinical Significance of Deformity of the Cecum in Amebi asis. Relialogy 1945 45 565

Decause several cases were encountered at Preby terian Hospital, New York City in which the first suggestion that amebissis was present came from the demonstration of a deformed excum the authors undertook a review of the records of the 110 cases observed at this hospital in which amebiasis was either proved or thought to be present. In 108 of these cases the endamosche histotytics was recovered either from stools or timpes in several of the remaining cases only one stool had been examined.

The cases were grouped into (a) or with diarrhea. (b) 15 with abdominal pain without diarrhea, (c) 54 with no significant symptoms directly referable to the intestinal tract, and (d) o in which there was inadequate information in regard to abdominal pain. Barlum examination was done in as of the cases with duarrhea, of which 18 showed a deformed cecum among the o cases with abdominal pain a cecal de formity was demonstrated in 3 among the 18 in group c a cecal deformity was found in 4, and among the 7 cases in group & a deformed cecum was discovered in 5 Hence, of the 67 cases subjected to colonic barium study 30 (45%) showed a cocal deformity and this finding occurred 5 times as frequently in cases with diarrhea or abdominal pain as in cases without such symptoms. In 58 of this group of 67 the endamoeba histolytics was demonstrated in the stools and its presence was not disproved in the other o Of these 58 cases sx (36%) showed cecal deformity while another case with deformed cecure and ascending colon terminated in clinical recovery only after a course of emetine. Two other cases of proved amebiasis showed deformity of the transverse colon and a third revealed rectal stric ture. Hence approximately 50 per cent of the patients examined and 41 per cent of those with endamoeba histolytica in their stools had definitely abnormal roentgen findings to per cent of these deformities were of the cecum. In only a cases showing a deformed cecum was there also an associated deformity of the more distal colon but in none of the cases was the terminal fleum narrowed or intrinsically distorted.

In the majority of cases of deformed occum, the creal outline was amonth, and in a few irregular. The deformity to be significant, should be permitted in some degree throughout the examination. In 4 of the 5 cases re-examined after therapy for smallash some decrease of the deformity was noted but in the infilt case in which shrinkage was extreme to change resulted. The authors believe that at test a portion of the reversible change is due to cecal

As regards the differential diagnosis the authors point out (1) that in the large majority of cases tuberculosis involves both the econs and fleum although hyperplastic tuberculosis of the escum could simulate the deformity described above (2) that regional Beltis commonly involves the fleum often with resultant narrowing and irregulatly of the terminal portion, but it attacks the recum must less commonly (3) that carrisoms of the ceesa nazually produces an irregular asymmetrical Elina defect often associated with a palpable mass quite different from the causally smooth walled contraction cecum of ameliasis but, of course shootd a must be formed by a large amelic granuloms, it could not be distinguished recentrespoterally from carrisons

The authors conclude that recognizable the formity of the eccum without involvement of the terminal lleum is likely to be present in more than a third of the cases of amebians and that this deformity is a clinically valuable sign not dispossite, but definitely suggestive of the disease. It absence, on the other hand is of no value in ruling out the disease.

Clute, H. M., and Kenney F R.: Primary Anastomods in Carcinoma of the Colon. England J M., 945 33 799.

Sixty five cases of carcinoms of the colon are reviewed. The total mortality was as por cent (6 deaths) in 34 cases with resection and immediate anastomosis there was a single death, or a mortality of 3 per cent. Eighteen cases requiring Mikulica resection had a 4 per cent mortality (4 deaths). Seventien inoperable cases upon which only pairs three procedures could be done had a mortality of 19 per cent (5 deaths). Of the deaths among the re-sectable cases, 1 was due to shock, 1 to coronary thrembooks and 1 to pollmonary embolisms.

These cases evaluate the feasibility of immediate restoration of the intestinal continuity following radical resection of carcinoma of the colon. The authors intended to evaluate the use of chemotherapy in the improvement of their results but became impressed by the numerous factors that had improved colon surgery They emphasize the value of preoperative and postoperative care. The treat ment of anemia and protein deficiencies is ac complished with adequate quantities of blood and the intravenous administration of amino acids before and after surgery The authors value the use of sulfasuxidine in the preoperative reduction of intestinal flora and because of its mild lavative effect, but note that cases in which it was not used presented equally good results in many instances. They have discontinued the preoperative use of drastic purgatives. Gastric suction is advised for a day before operation and is continued postopera

tively until the return of normal perintalisis. The authors favor radical removal of the tumor and of the lymph glands draining the involved segment of colon. The Milkulies and other obstructive resections have been relegated to cases in which the risk is poor with partial obstruction or some degree of infection obscurace to can be done questly and the bowel is simultaneously decompressed. Resection and immediate anastomosis are preferred because of the many advantages to the patient, such as the elimination of spur crushing and of the an

noyances associated with a colostomy anastomosis has not increased the mortality. The authors did not use many eccostomles but believe that eccostomy is a worthwhile procedure to protect the anastomoses distal to it in the colon and to de compress the obstructed colon which eliminates the necessity of resection for the obstruction

The article presents the advances made in colonic resection in the last few years particularly since the introduction of drugs reducing the incidence of infection and the greater knowledge of fluid balance and of total nutrition of the surgical patient. FREDERICK C. HOEBEL, M D

### LIVER, GALL BLADDER, PANCREAS, AND SPLKEN

With, T K.: On the Occurrence in Human Serum of Yellow Substances Different from Billrubin and Carotenoids Acia med scand 1945 122 501

The author has described a method for the quantita tive estimation of the nonbilirubin yellow substance in serum by means of the Pulfrich photometer Investigation of the spectral absorption of pure solutions of bilirubin and solutions of bilirubin in serum were carried out, and it was shown that the proportion between the extinction of the diazo re action with filter S or and that of the spectral absorption of bilirubin with S.43 in the Pulfrich photometer (E 61/E.43) for solutions in serum had a constant value with only little variation from one

The determination of the proportion E 61/E-43 serum to the other of different sera showed values considerably below the characteristic value for pure bilirubin serum Consequently the solution for most of them regular occurrence in human serum of yellow substances different from bilirubin is to be looked upon (by the author) as an established fact. It was also demonstrated that the concentration of these yellow substances in serum was of the same magnitude as the bilirubin concentration. It exceeded the con centration of the serum carotenoids considerably Further it could be demonstrated that hemoglobin or biliverdin could not be the cause of these findings

The chemical nature of the nonbilirubin yellow substance and its physiological properties are discusted and the hypothesis is advanced that in human serum it is identical with the xanthorubin of he patectomized dogs and with the pyrrol compounds bihfuscan or mesobihfuscin David H LYNN M.D

### Clagett O T., and Hawkins, W J : Cystic Disease of the Liver Ann. Surg 1946 123 111

Simple solitary cysts of the liver are localized and urually circumscribed, and occasionally they possess a pedicle. The result is that surgical treatment is far more often possible for solitary cysts than for cystic disease, wherein the lesion is more generalized with

The authors patient was a married man 39 years reference to the liver of age. His chief complaints were a feeling of full

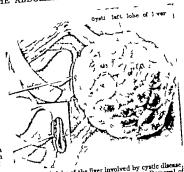

Fig 1. Left lobe of the liver involved by cystic disease, tourniquet applied around its pedicle. Inset Removal of left lobe of liver and closure of peckele with interrupted mattress sutures. (Courtesy of J. B. Lippincott Co.)

ness and dull aching in the epigastrium. This dis tress had been present for 4 years. The symptoms progressed until at the time of his examination at the clinic, he was aware of a large mass in the epi gastrium and was unable to ingest even a moderate amount of food without feeling discomfort. In spite of the normal results obtained in investigating the pancreatic function, it was thought that the epigastric tumor was probably a pancreatic cyst.

Accordingly on August 12 1944 operation was performed through a primary upper left rectus incision. Immediately a portion of the mass con assuing of multiple various sized cysts presented itself into the incision. On further examination it was found that this represented the left lobe of the liver Examination of the right lobe showed it to be normal in appearance. Palpation of both kidneys was then done and neither seemed to be cystic. By separating numerous adhesions from the mass, a relatively narrow pedicle was encountered adjacent to the ligamentum teres. A Bethune pneumonec tomy tourniquet was then applied around the pedicle (Fig 1) and the entire left lobe of the liver was removed en masse. The remaining stump was closed with interrupted chromic catgut sutures The tourniquet was then removed and there remained only minor coming of blood from the stump

Five grams of sulfanilamide powder were aprinkled into the area and one double iodoform pack was placed to control what ooring might occur from the stump Two Penrose drains were brought out through the incusion. The specimen included the entire left lobe of the liver consisting of multiple cysts lined by epithelium of the bile duct type. The postoperative convalescence was uneventful.

As iar as the authors were able to determine from the literature, this case is the first one reported in which the entire left lobe of the liver was removed for cystic disease. The only other reported case of a similar nature was that of von Haberer who in 1905 removed the entire left lobe of the liver because of a nonparasitic solitary cyst which occupied the greater part of that lobe.

Most authors agree that the cause of the simple solitary cyst is some form of local obstruction in the biliary tract with a resultant retention type of cyst. In cystle disease however opinion seems to be divided since there are various hypotheses as to its

pathogenesis.

All of the articles reviewed make special mention of the fact that cystic disease of the liver is usually associated with cystic disease elsewhere—notably in the kidney. When there are associated renal lesions, they are usually far more advanced than the lesions in the liver.

If a cyatic liver has enlarged to the point of cataing a palpable mass, the identity of which cannot be proved then exploration of the abdomen is advasble. When such a lesion is encountered two alternatives are possible (1) the involved portion can be removed or (a) nothing should be done. The decision to excess the lesion must be made only after several factors have been considered. The kidneys abould be palpated. If they too are involved seriously then there is no point in attempting to excise a portion of the liver the hazards of this procedure are well recognitive.

If the patient has been asymptomatic in spite of the presence of the cyatic liver and if removal of the tumor would involve too great a risk, then one hand, the tumor is interfering with the patient's well being, the kidneys are without palpable involvement, and removal of the lesion would not be too hazardous a procedure, then extirpation cer tainly is justifiable.

### Mirizzi, P L.: The Diagnosis of Choledocholithiasis (Diagnostico de la colédocolitissis) Preus méd.

argent 1045, 3 #039. The value of the usual preoperative clinical and laboratory procedures for the detection of stone in the common duct and/or the adjacent hepatic bile passages is admitted, but the author deprecates the fact that they should play more than a modest role in the integral degrees of choledocholithiasis. Attempts at preoperative filling of the common bile duct with shadow producing medium by reflux from the duodenum (duodenal catheterisation) is mentioned without enthusiasm and as being only rarely successful Even the nonsurgical cholangiography of Lee of Philadelphia, whereby the gall bladder is injected with a shadow medium through a peritoneoscope is regarded askance as being ementially a surgical procedure, as being applicable to not more than to per cent of the gall bladders, and as being of uncertain innoculty because it leads to billary peritonitis and other accidents. In fact, all of these procedures pale in significance in face of the inescapable duty of the surgeon, not only to arrive at the diagnosis of choledochothitas, but also the centum that the patient has been freed of all the normal that the patient has been freed of all the normal that the bile duct. Even laparatomy with discreptions of the choledochots, choledochotomy with maximental probleg of the bile passages and perhaps the choledochotomy of McLiver are not without objections, and although of add in determining the presence of canalicular lithiasis in a large proportion of cases, they do not afford an absolute diagnosis.

Operative cholangiography on the other hand has contributed extensively in confirming the diagrams of stone in the bile tracts it is a valuable source of information in lithiaris of the ampulla of Vater and intrahepatic stone it furnishes capital data on the psuedotumoral form of choledocholithians, and represents an irreplaceable recourse for providing assurance that all of the concretions have been re moved from the principal bile duct. In the case of the calculus located at the ampulla of Vater even when it is too small to show on the film as the usual nunch press defect at the lower end of the common bile duct (where the usual outline of the amoulla would be expected) or as the less common defects such as the right angled uncoform parrot beaked. festooned and angulated defect appearance, its presence will at times be suspected by the refux into the duct of Wirsung-which is more persistent than in the cases of simple dystonia of the sphincter of Oddi.

This question of negalstence, however, also brings up the matter of the functional criterion in the roent genological examination of these patients, that is, the taking of one or more cholangiographic exposures following the original one. For instance, in I patient of the author's material, the first film disclosed a typical inflammation of the sphincter of Oddi with the usual "Havana cigar" tip to the ampulla another film was taken and this proffered the classical image of calculus of the papilla (punch press defect) with injection of the duct of Wirsung in another the first exposure depicted a punch press defect, while the subsequent film showed the condition to be normal. Of course, the taking of two, or of several films at varying intervals is not of itself sufficient to solve all the problems in stone in the bile ducts frequently all attainable facts will have to be mar shalled to arrive at a correct diagnosis.

In a patient a history of persistent fectors caused the author to emplore the nonlilling left hepatic duct where, in spite of the fact that hepatic duct storas are nearty always multiple, and primary store in the hepatic duct without accompanying involvement of the common duct is a great curiosity a single large stone, the shape of a Winchester bullet with nonpointing downward was extracted from the hepatic duct. After this the hepatic system filled normally with shadow medium. At operation in this case the choledochus was found to fill and empty into the duodenum in an unonstructed manner.

However stone is not the only condition preventing the filling of part of the bile tract during the operative cholangiographic examination. It may be necessary in addition to injecting the shadow mix ture through the gall bladder or the stump of the cystic duct, to open the choledochus itself and make an injection through the choledochotomy opening Or it may even be necessary to provide the injecting syringe with a filiform catheter and push this into the different sections of the ble tract system. This is likely to be necessary in the dilated and distorted passages of the longstanding recurring case of gallstones.

Even if all methods have been exhausted without an explanation of a longstanding clinical history of mechanical licterus one is still justified in suspecting an obstruction below any of those uncovered a concretion in the ampulla of Vater a stenosing pancreatitis or inflammation of the sphincter of Oddi. In any case the ampullar stone is the more probable, and one is justified in resorting to a transduodenal

papillotomy

One of the most difficult problems is the different ation between the obstruction due to stone accompanied by a psuedotumor that is the matting together by adhesions of the epiploon, colon gastric antrum and pylorus pancreas and bile sac, and a true neoplasm. Here again however the author holds that operative cholanguography will be of assistance, in that in the obstruction by stone the injected shadow material surrounds the concretion and reveals the lacunar characteristics of this form of obstructing body while in the neoplastic type of block the hindrance to the flow of fodo-acetate will be complete.

John W Brennau, M.D.

### Robertson H. R.: Silent Gallstones Gastrocateral #17 1945 5 345

The author gives a very comprehensive historical review of the literature concerning gall atones. He surveyed the results of postmortem studies of the gall bladder made at the Mayo Clinic during the 10 years from 1934 to 1943 on persons over 20 years of age A total of 1,027 had gall stones 497 males and 530 females In this study no attempt was made to determine the percentage of patients who at post mortem did not have, and apparently never had gall stones The author with a coauthor found that of 16,036 postmortem examinations at the same chnic in the years from 1910 to 1942 16 3 per cent (12 6 per cent in males and 22 6 per cent in females) revealed that the person had or had had gall stones In the present review the histories of these patients were carefully reviewed and it was found that in 626 (61%) there apparently had been no suspicion by the patients or their attending physicians that gall stones had been present. The remaining 400 cases could be fitted into various and sometimes over lapping categories for example, 305 of the patients had undergone one or more operations for gall stones while in 80 cases stones were discovered accidentally at laparotomy for some other condition.

The assertion by some physicians that a certain percentage of silent gall stones in any given series

is a reflection on the diagnostic abilities of the at tending physicians is unwarranted. After gall stones have been accidentally discovered the at tribution of the symptoms and signs to their presence is not always on a sound clinical or pathological basis. About 50 per cent of gall stone cases remain unrecognized. Not all gall stones discovered during life warrant operation for their removal they are an individual problem in each instance and are usually accorded that importance which the best welfare of the patient warrants.

EARL O LATIMER, M.D.

Skelton, M O and Torey G H Congenital Obliteration of the Bile Ducts and Icterus Gravis Neonatorum Brit M J., 1945 2 914

The authors state that icterus gravis neonatorum and congenital obliteration of the bile ducts may both be associated with biliary obstruction. In the former condition the canaliculi may be plugged by bile thrombi probably as the result of damage of the hepatic cells Once these thrombi have formed they may aggregate to produce an obstructing mass in the extrahepatic bile ducts the final effect being to add an obstructive element to the jaundice caused by the hemolysis Occasionally the biliary epithelial cells become swollen and this tends to aggravate the condition Desquamated epithelial debris lying free in the lumen of the bile ducts may add further to the obstruction In some cases of icterus graves of long standing biliary stasis may occur and produce a picture of hepatic cirrhosis which is very similar to that of congenital obliteration.

Two cases of interns gravis are described, in which obstruction was believed to have been due to blocking of the large bile ducts with inspissated bile. In one case the plug was dislodged at operation. The fathers of both patients as well as the patients themselves were thesus positive. The mothers were rhesus negative with Rh antibodies in their blood.

The authors describe 2 other cases of congentral fibrosis of the bile ducts, in both of which there was a rhesus incompatibility demonstrated in the parents. Two siblings of one of these parents born subsequently died of jaundice. The findings at autopsy included crythropolesis and keructerus in

both cases.

It is not suggested that all cases of congenital obstruction of the bile ducts are associated with erythroblastosis fetalis but the fact that some of them appear to be associated with intereus gravis meanatorum is of practical importance. Consequently any family showing a history of congenital obliteration should be examined for evidence of thesus incompatibility. Only in this way can preparations be made to anticipate hemolytic disease which may occur in subsequent children.

As a prophylactic measure in patients with icterus gravis, the practice of massage over the region of the gall bladder is recommended in the hope of avoiding plugging of the ble ducts and hence obstructive THOMOGEN B MASSET, MLD

Smith H G., Pratt Thomas, H. R., and Mace, L. M : Re-Establishment of Pancreatic Secretion into the Intestine after Division of the Pancreas; An Experimental Study Arck Surg 1945 TI 164.

As a result of progress in the radical operative treatment of carcinoma involving the head of the pancress and the periampullary region, pancreatic cancer can be approached today with a clearer concept of the operative technique and with a reason able chance of accomplishing a surgical cure

Despite widening experience with this difficult surgical problem, the incidence of postoperative complications remains high Some of the more distressing postoperative sequelae are referable to the stump of the divided pancreas and consist of external pancreatic fistula, acute pancreatic necrosis retention cyst, and chemical or "enzymatic peritonitis. The pancreatic stump has been handled generally speaking by one of two methods occlusion by inversion of the sutures with or without ligation of the duct of Wirsung and some form of pancreaticoenterostomy in which the stump is im planted into a seament of intestine. As regards the arst method digestion of the inverting sutures occurs all too frequently with resulting leakage of the pancreatic fuice and the consequent development of one or more of the complications mentioned. As to the second method the question has been raised whether reimplantation of the pancreatic duct into the gastrointestinal tract is necessary inasmuch as it is well established that many patients live normal, healthy lives after being deprived of the external secretions of the pancreas. On the other hand, many such patients suffer severely from disturbances of fat direction in the form of steatorrhea and malnutrition so that it is important, whenever possible to maintain the external accretory function of the An evaluation of techniques of pan creaticoenterostomy employed by various investi gators directs attention to two important factors

all procedures (with the exception of Cattell's simple method) involve an open anastomosis, with a consequent breach in asepsis and most of them are too time consuming This experimental study was conducted in order to develop an aseptic technique which can be performed with minimal loss of time and

preservation of the external pancreatic secretions. Experiments were done on as dogs. In 15 animals the pancress was divided at the junction of the uncinate process and the body without disturbing the relationships of the latter to the duodenum and thereby leaving the junction of the main pancreatic duct intact. The exposed transected surface of the pancreatic body was closed with sutures after ligation of the duct. In this manner the uncluste process was isolated entirely from the remainder of the gland, and its independent blood supply was main tained. The divided end of the duct in the uncinate process was allowed to retract into the parenchyma of the gland without its being ligated. The stump of the divided uncinate process was then implanted

into the jejunal wall in an incision that extended down to, but not through, the jejunal mucosa and was made secure in the journal wall by fine snimes. The remaining 7 animals were operated on by a modification of the technique of Cattell. The procedure was similar in detail to that described event that the unclnate duct was desected free so as to protrude from the divided stump of the gland. A crushing ligature of fine surgical gut was tied about the protruding duct and one end of the ligature was passed as a suture through the exposed februal submucoes and tied firmly to the other end which brought the duct against the mucosa in a firm necrotizing ligature. The pancreatic stump was secured into the februal wall in the usual manner All animals survived and remained in good coodstion. Observations of the state of the pancreaticoenterostomy were made at intervals varying from f to 48 days by the following technique

The abdomen of each dog was reopened under anesthesia and the jejunum adjacent to the pan creatic attachment was opened widely which ex posed to inspection the jejunal mucosa at the site of the pancreatic implantation. A concentrated. highly active preparation of secretin was then infected into the vena cava. If a fistula had developed from the uncinate stump into the jejunum pancreatic juice could be seen grossly dripping from the fistular onlice in the mucosa. If fistula formation had not occurred no response to the secretin was noted. The potency of the secretin was tested by opening the duodenum and observing simultane ously the flow of bile and pancreatic juice from the ampulla of Vater Of the as animals studied, 15 showed definite secretion of pancreatic juke at the pancreaticojejunal junction after the intravenous

injection of secretin.

After the functional status of the pancreaticoiciunal function had been determined, the entire unclosite process and the attached felunum were excised for microscopic study with particular ref erence to acute pancreatitis pancreatic fibrosis, and the development of pancreaticojejunal fistules. None of the animals showed gross evidence of active peritonitis or fat necrosis. There was some evidence of acute pancreatitis in 17 per cent of the animals but pronounced diffuse pancreatitis was found in only a animals. Each of these animals appeared to be quite healthy. Some degree of scar theue formation was demonstrable in or per cent of the animals but fibrosis was considered pronounced in only I animal. This animal presented an indurated and atrophic stump but no microscopic evidence of fistula. Despite these findings, the response to secretin was positive although the flow of pancreatic juice was aluggish. Definite marroscopic evidence of a function between the mucosa of the uncinate duct and the mucross of the jejunum was detectable in 50 per cent of the animals. It is pomted out that a fistula may exist despite failure to demonstrate it microscopically by the secretin test and also by the injection of water through the

uncanate duct into the jejunum. No external pan creatic fistula was encountered and only 1 retention cyst which complicated the procedure was found form L. Lampourst. M.D.

Varco, R. L.: A Viethod of Implanting the Pan creatic Duct into the Jejunum in the Whipple Operation for Carcinoma of the Pancreas. Surgry 1945 18 569.

The author presents a technique for anastomosing the pancreatic duct to the bowel in cases of resection

of the head of the pancreas. This procedure has now been successfully carried out in a patients

The pancreatic duct is isolated with a short extra glandular section preserved when the gland is transected. Two time like sutures are placed in the wall of the duct to hold it open. A two-holed catheter somewhat larger than the duct is selected—about a size 12. Eight centimeters of the catheter are stretched over a Keith skin needle which serves as an obturator and impaled at a point on the catheter wall slightly eccentric to the tip. 1s the segment of

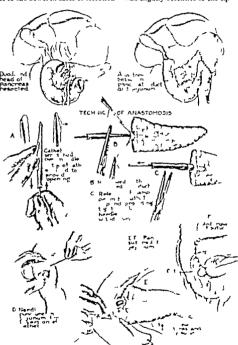

Fig. 1. The two drawings is the top indicate approximately that in field by malagnancy and diagram the reservation from a fit of the set of trace during lasted on the Dean split of concation for any some of the lasted the punctual. The technique of implanting the panetratic duct but the figurum is shown in additional to the figurum is shown in additional to the figurum is shown.

catheter is stretched over the obtunator its transverse diameter is decreased. It is held stretched by clamping the tube and obturator firmly with a hemostat. An oblique section is now cut from the tube, care being taken to place this distal to the tented will of the catheter. The stretched catheter is alipped a short distance into the pancreatic duct and on release of the hemostat the catheter is permit ted to resume its normal diameter and it is smally held in the duct. A fine ligature may if desired be used to hold the extraglandular duct against the catheter, but usually this is unnecessary

With fine sutures the posterior capsule of the pancress is sutured to the jojunum at the site selected for susatomesis. A fine puncture hole is made with a Kelth needle through all layers of the howel will and the catheter is forced through this small puncture wound into the humen of the howel, which gives a very close fit. Two fine sutures are placed between the connective thruse adjacent to the duct and the serous next to the puncture site. The remainder of the capsule of the pancress is sutured to the bowel serous, nextly the antioprosphere.

In 4 cases in which this method has been used there has been no pancreatic fistula.

EARL O. LATINGE, M.D.

Wakim, K. G., and Mason, J W: The Effects of Adrenalin and Nambutal Anesthesia on Blood Constituents Before and After Splenectomy J Les Clin. H 946, 31 8

The authors studied the effect of adrenaline and of membraia mesthesis on the concentration of hemoglobin and plasma protesms and on the red and white blood cell counts in intact and splenectomized dogs. The lateral surface area of the spleen was determined under nembraia mesthesis before and after the administration of adrenaline.

They found that the intravenous administration of adminish increases the concentration of hemoglobin and the red cell count in the circulating blood to a much prester extent in instact than in sphenomized dogs. Nembutal anexthesia cames hemofilution with a reduction in the hemoglobin concentration and in the red cell count, and a slight reduction in the plasms protein concentration. The size of the pleen in dogs under nembutal anexthesia was decreased about 60 per cent by the intravenous administration of adrenaline. The blood squeezed out by the spleen during its contraction under the influence of adrenaline had an average hemoglobin concentration about 11 per cent higher than that of jugular blood.

#### MISCELLANEOUS

Bradford, B., Jr., Battle, L. H., Jr. and Passchoff S. S.: Abdominal Surgery in an Evacuation Hospital. A s. Surg. 1946, 3 32

The observations presented were made on 341 abdominal war wounds operated upon in a single evacuation hospital from the middle of June, 1944

through December 1944 in the European theatre. The distance of the hospital from active finite varied from 4 to 30 miles. The cases included all of those with penetrating and perforating wounds to volving the peritoneum perforating wounds of the rectum and major retroperitoneal injuries requiring cellotomy.

The diagnosis of intra-abdominal perforation was usually obvious in battle casualties. Signs of peritoneal irritation were frequently absent during shock, but appeared when it was relieved. Symptoms of peritoneal irritation appeared late in wounds of the left colon, and a silent abdomen was the rule when peritoneal irritation was present. Shoulder pain was not important, and the absence of liver duliness was not a constant finding. Proctoscopy and sigmoidoscopy were invaluable in uncovering rectal and algoroid perforations. Location of the foreign body roentgenologically was helpful. Urin alyais was a routine procedure in all cases of ab-dominal injury and with cathetensation was useful in exposing wounds of the urinary tract-When in doubt as to whether intraabdominal per foration existed, an emboratory laparotomy was done.

Preoperative management is stressed as being frequently the decisive factor in the outcome of cases of abdominal injury. All patients were sent to the shock ward first, whether shock existed or not-Both blood and plasma were used but the former was believed to be of most value and a quantity of I liter or more was usually necessary to relieve shock in individual cases Patients with active intra abdominal bleeding and abdominal evisceration were sent directly to surgery with blood running because they did not respond to shock therapy untisurgery was done. In judging the optimum time for surgery the patient's general condition and skin warmth were valuable aids. Single blood pressure readings were misleading but multiple readings were helpful. However patients with a blood pressure of below 80 systolic did not tolerate surgery well. The time interval before surgery was not found to be important except in cases of continued bleeding and evisceration at intervals and some patients under shock therapy were operated upon as late as 36 hours after injury however the policy was to give all patients the benefit of surgery whether or not they responded to shock therapy

The mortality in the cases of patients who were operated upon 6 hours from the time of injury was 30 per cent. The mortality dropped in the subsequent air hour periods until at the 24 to 8 hour period it was but 10 per cent. The high early mortality was partly explained by the fact that the most deperate cases were operated upon first.

Where multiple major wounds existed the policy was to perform the separate procedures over a period of days rather than have several operative teams working at the same time.

#### MISCRILLANEOUS

Bradford, B., Jr., Battle, L. H., Jr and Passchoff S. S.: Abdominal Surgery in an Evacuation Hospital Ann Surg 1946 3 3

The observations presented were made on 341 abdominal war wounds operated upon in a single evacuation hospital from the middle of June 1944

through December 1944 in the European theatre The distance of the hospital from active fighting varied from 4 to 30 miles. The cases include all of those with penetrating and perforating wounds in volving the pentoneum perforating wounds of the rectum and major retropentoneal injuries requiring celestomy

The diagnosis of intra-abdominal perforation was usually obvious in battle casualties. Signs of pentones irritation were frequently absent dunor shock, but appeared when it was relieved. Symptoms of peritoneal irritation appeared late in wounds of the left colon, and a silent abdomen was the rule when peritoneal irritation was present. Shoulder pain was not important, and the absence of liver duliness was not a constant finding Proctocopy and sigmoidoscopy were invaluable in uncovering rectal and sigmoid perforations. Location of the foreign body roentgenologically was helpful. Unnalysis was a routine procedure in all cases of abdominal injury and, with catheterization, was useful in exposing wounds of the unnary tract. When in doubt as to whether intraabdominal per foration existed an exploratory laparotomy was

done Preoperative management is stressed as being frequently the decisive factor in the outcome of cases of abdominal injury. All patients were sent to the shock ward first, whether shock existed or not. Both blood and plasma were used, but the former was believed to be of most value and a quantity of I liter or more was usually necessary to relieve shock in Individual cases. Patients with active intra abdominal bleeding and abdominal evisceration were sent directly to surgery with blood running because they did not remond to shock therapy until surgery was done In judging the optimum time for surgery the patient's general condition and skin warmth were valuable aids. Single blood pressure readings were misleading but multiple readings were helpful. However patients with a blood pressure of below 80 systolic did not tolerate surgery well. The time interval before surgery was not found to be important except in cases of continued bleeding and evisceration at intervals, and some patients under shock therapy were operated upon as late as 36 bours after injury however the policy was to give all patients the benefit of surgery whether or not they responded to shock therapy

The mortality in the cases of patients who were operated upon 6 hours from the time of injury was 30 per cent. The mortality dropped in the mbsequent six-hour periods until, at the 24 to 30 hour period, it was but 10 per cent. The high early mortality was partly explained by the fact that the most desperate cases were operated upon first.

Where multiple major wounds existed the policy was to perform the separate procedures over a period of days rather than have several operative teams

working at the same time.

In most cases the anesthetic of choice was nitrous oxed oxygen, and ether in a closed system, prefer

ably with intratracheal intubation. Open drop ether was valuable for patients in severe shock from aternal hemorrhage. Spinal anesthesia and pento-

thal were unsatisfactory

In combined chest and abdominal woun! the therace problem was handled first. The tran therace approach to the disphragm was most useful in treating wounds of the disphragm splicen and is registrict wounds. Paramedian incident with separation of either of the recti muscles were used the frequently. Exposure through subcostal memors proved very useful expecially in cases with inunes of the stomach liver and splicen and the hybride and splient flexibits of the colon.

The authors state that systematic examination of the abdominal contents is important. Suture of wounds of the small bowel is preferable to resection and end to-end suture was the procedure of choice fillowing resection. Enterostomy of the small

lowel should not be done.

Small wounds of the cecum and ascen ling colon were sutured and a large Pezzar catheter was paced in the cecum as a safety valve. In the transverse descending and sigmoid colon the Milail cet preferably the loop-type of colorsoms was performed. In rectosigmoid perforations, those within the pertoneal eavity were sutured with a proximal

inguinal righeid stomy to divert the local stream. In extraportionial perforations of the tectum all quate drainage with removal of the coccyal if necessary and appears and a presumal come my were dominated as a second stream.

Wound of the liver were managed by packing or the up of free mode graft. Wounds of the phoen

usually required in cheeterny

Abdominal incides were carefully closed in layers and reconcerned with sill, or wire retention solutions. Drainage of the peritorical casety was unnecessary except in call solutions of the liver.

Fortoperative care it cluded adequate highest of and the liberal in of jama and who libed to maintain libed protein levels. Warren treas raining was used it utiled in all portoperative adominal care. Pit, it mill ewa given prophulactically in the immusite postererative periodical of and toutiled in all care and is given populate trailiby in the immusite postererative periodical viation. Can't thinking were given orally. Levelilliby was used trout rely in all cares and is given partial credit for the low incidence (16 per cent) of pull many infection. ### GYNECOLOGY

#### UTERUS

Eisen, D., and Goldstein J : Linkodol Intravagation during Uterosalpingography with Pulmonary Compileations. Radial gr 1943 45 603

The accidental intravasation of lipiodol into the venous system of the uterus during uterosalplingog raphy has been repeatedly described in the litera ture. As a rule there were no fil effects except perhaps slight temporary leucocytosis. In rare cases pulmonary and cerebral embolism and pulmonary infarction were noted

In an attempt to study the mechanism of uniodol embolism in the lungs Sicard and Forestier in fected from 2 to 4 c.c. into the cubital vein. The liplodol reached the lungs in 5 or 6 seconds remained there for from 6 to 8 minutes and then suddenly disappeared. The only effect in the pa-tient was a slight cough. Walther injected liploids into the ear vein of rubbits. He found that practi cally all of the oil became arrested in the lungs where

Lipiodol I travasation t th aterine venous olexus and the ovarian ver The latt re-emble preters. pring filled ther entirety on the right sid t the vena cava and on the left up to and including the renal vein.

it underwent two processes. The major part was broken up into lodine and fat the lodine being er creted through the kidneys during the first \$ days as potassium folide and the fat being saponified and carried away by the circulation. A smaller part of the liplodol became phagocytosed. Walther also suggested that an inflammation may develop around fat droplets because of bacteria carried along by the lipiodol from the uterus

A review of the literature revealed that the various authors attributed the intravaution to traums of the endometrium during the injection, to excessive pressure and to an increased permeability of the receiving sinuses, such as is observed in idlopathic uterine bleedings or immediately after

menstruation.

The authors themselves noted intravasation of liplodol during uterosalpingography in a woman 25 years of age. The case is briefly described and illustrated (Fig. 1) The afternoon after the injection the patient developed a dry cough with a temperature of 102 degrees. The next day her cough increased and she brought up bloody sputum. The temperature remained high until the fourth day when it dropped to normal. The cough persisted, however and a roentgenogram of the chest on the ninth day revealed a dense patchy opacity involving the lower two-thirds of both lunars. Another rocat genogram a month later howed practically a normal

appearance in conjunction with this case the authors rec ommended the following precautions (t) uterosalningography should not be performed sooner than from 8 to 10 days after the menstrual period or any operation on the uterus (2) the position of the uterus should be determined preliminarily by the use of a sound and in case of angulation the injection should be done by properly circumventing the angulation so as to a old trauma to the endometrum (3) the pres ure of the injection should not exceed from 1 to to 200 mm of mercury a manometer being used for control and (4) the amount of lipsodol injected should be no more than is necessary to fill the uterus and tubes with a slight spill.

T LILECTE M.D.

Morris, P.: Hydrometrocolpos in Infancy—A Cause of Urinary Retention Intestinal Obstruction and Edema of the Lower Extremities. Am J 11 945 0 75

1 7 weeks old girl who had been pa sing thin ribbonlike stools with difficulty for about 3 weeks, and f r a day had only slightly wet two dispers, suddenly leveloped swelling of the feet and a pur plish discoloration of the lower extremities. Also th pre your day blood flecks had appeared in the stool and intus usception was suspected because of the presence of a mass in the lower abdomen. In addition to the large cystic mass extending upward from the publs and apparently slightly more toward the right side reaching to 2 cm. above the umbilicus, there was a peculiar bulge at the vulva, cystic in appearance, pointing anteriorly and somewhat resembling a rectocele with the distended viscus pushing into it.

At laparotomy after the bladder had been emptied by eatheterization a second mass appeared behind it. This was recognized as the distended uterus and vagna. Pressure on this mass, which was only about 5cm in diameter caused an increased tension in the vulvar bulge which was then incised externally. A considerable amount of a thin alightly milty fluid excaped and the mass collapsed, which allowed the rest of the urine to be emptied easily from the blad der. The fluid contained some white blood cells but the culture was sterile. The child died about a week later death apparently having nothing directly to do with the abnormal conduction reported.

The author thinks that patients with hydromet recolpos should not ordinarily be subjected to laparotomy as simple meason of the vaginal mem brane entirely relieves the condition. Preluminary sapiration by needle of some of the cyst fluid and in petion into the cyst of so e.e. of diotrast followed by anteroposterior and lateral roentgen ray views (as suggested by Mahoney and Chamberlain U Pediat, 1940 17, 172) will clearly establish the diagnosis of

the condition.

The author wonders if many of these patients are not escaping detection as the condition becomes more or less quiescent about a weeks after birth when the glandular activity of the vagina and cervix regresses with exhaustion of the store of circulating estrogen left by the mother. With an imperforate condition of the hymen or residual embryonic vaginal septim as the case may be, the condition may develop again about the time of puberty and lead to the later development of the not infrequently observed hem atocolpos of the adolescent girl.

TOUR W BRENMAN M.D.

Caivo M and Botelia, J: Hormonal Conditions in Uterine Myoma and the Genesis of the Men strual Disturbences in Myomstons Women (Sobre las condiciones hormonales en el mioma de diero y la génesis de los trastomos menstruales de las miomatosas) Re at pless. 661, 1045 3 87

This article is the third of a series of publications by these same authors in preceding numbers of this same journal, of which the first (Calvo y Botella Rev expan. obst. 1944 : 1) demonstrated the predominance (four fifths of the patients with myonns) of incomplete cycles that is persistent follicles and snovular cycles The second (fibil 1944, 1 165) showed that in almost three fourths of the myonations women the secretory phase of the menatural cycle did not develop These findings corresponded closely to those in the first article. In addition the reader is referred to the thesis of one of the authors (Calvo Marcos Tesis doctoral, Madrid 1943) for a

detailed discussion of the techniques employed in this series of investigations.

In the two previous articles the investigations had led the authors to believe that there is actually an inundation of the blood of the myoma patient by estrogenic hormone vis that the blood hormone is higher than normal, although the excess seems due rather to a constancy of secretion (anovular cycle) than to a high titter at any one phase. This constancy of secretion is designated by the authors as a rhythmic hyperestronism. It also seemed to them that the pathological bleeding so characteristic of the myoma has a functional origin that is it is bound up with the endometrial functional changes incident to normal meastruation.

In this report, on the other hand there are presented the shortcomings in the authors findings militating against unqualified acceptance of any such

conclusions as those just cited

The urine of 8 myomatous patients was tested for the elimination of estrogenic hormones on castrated adult white mice according to the method of Siebke and, although it is admitted that the urinary estrogenic elimination is not now regarded as a reliable criterion for inducating its level in the blood it was found that the urinary elimination was neither constant nor excessive. In only 2 instances was the titer higher than normal and even in these cases the excessive elimination was not very marked and the tentative inference is offered that the endocrine disturbances of the myoma are due rather to the continuity of follicular secretion (anovular cycle) than to an actual increase in quantity at any particular time.

In studying their material the authors found that the incidence of the various patterns of menstrual manifestations in myoma showed in accord with practically all statisticians on this subject, a rather striking correlation of figures under all conditions. In their own material there was more than 50 per ent of patients complianing of menorrhagias more than 10 per cent with metrorrhagia, 3 per cent with eumenorrhagia and 4 per cent with amenorrhag, and these proportions of characteristic manifestations were maintained except perhaps for a slight predominance of copious menorrhagias in the frankly hyperplastic endometrial specimens no matter what endometrial phase was present.

The authors therefore, conclude from these studies that the bleeding in these myomatous patients is not due to a hormonal metropathy but rather to a vascular condition. In conformity with the older theories it is believed that it is due to the power of the myomatous new growth to induce congestion and changes in the capillary walls in the trissues overlying and contiguous to it. This perhaps is dependent upon its ability to produce some substances such as histamine or histaminoid substances and the effect is perhaps more or less sustained by the poor contractifity and cavity deformation which is presented by the uterus itself

JOHN W BREMMAN M.D.

### ADDEXAL AND PERUITERING CONDITIONS.

Jones, G. E. R., and Te Linde, R. W.: The Cure. bility of Granulosa Cell Turnors. 4m J Ohn 045 50 601

Three cases of granulosa cell tumors have been reported in which recurrences developed not less than 14 years after the original operation.

All 3 patients died 18 20 and 21 years respectively following the removal of the primary tumor in spite of the fact that the tumors were well encapanlated and showed no evidence of metastasis or implantation at the original operation. One tumor recurred in spate of bilateral salpingo-conhorectomy and bysterectomy

One case, with widespread inonerable abdominal metastases, responded well to deep a ray therapy over a period of 3 years, but a subsequent recurrence of the growth proved refractory to treatment.

The total urinary estrogen values in 2 cases were not extremely high but stood within the range of values for pormal cyclic women. However the values were well above those usually found in the authors laboratory for postmenopausal women. All 3 of the patients fell into this are group at the time of the tumor recurrence. All 3 cases exhibited clinical signs of estrogenic activity at that time

EDWARD L. CORNELL, M D

Usandizata M: Tumors of the Round Litament Los tumores del ligamento redondo) Rer eres obn 1945 3 75

The author's patient was a woman of 39 years who had been married for 18 years and had gone through a pregnancies with normal childbirth in each instance. She entered the Provincial Mater. nity Hospital at Zaragoza with progressive enlarge ment of the abdomen since about 5 months pr viously and rather mild pains in the hypogastrium radiating into the lumbosacral region.

Examination revealed a hypoga tric mass some what smaller than the head of an adult person of hard consistency very firmly fixed and with an irregular modular surface. The impression of a mall retroposed uterus was also obtained. The diagnosis was that of an intraligamentary solid tumor

At operation a tumor mass was uncovered it was somewhat smaller than an adult man a heart with multiple lobulations and of firm consist new it was situated almost entirely beneath the peritoneum The mass appeared t be in direct continuity with the uterine end of the round ligament in the right side the legament passing intact from the uterus i r about 3 cm before being engulfed by the tumor ma s. The broad ligament was well preserved the tube and ovary of that side presenting a normal appearance The peritoneum was freely movable on the surface of the tumor and the latter was easily enucleated The uterine segment of the round ligament was sectioned and the enucleation carried to the region of the internal inguinal ring where a small vascular pedicle was likewise cut and tied. The tumor could then be lifted out and the exact impression was given as though the round ligament had been excited between ligaments for its entire extent. This was followed by peritonealization, closure of the abdomenand an eventiers postoperative course.

Histological examination of the tumor disclosed that its texture consisted of abundant trabeculae of smooth muscle cells in a framework of fibrone ti sue.

In extensive bibliography is appended to this report of an extremely rare form of tumor

#### EXTERNAL GENITALIA

Oulnet A : Tuberculosis of the Valva and Cervis-Contribution to the Medical Statistic of Brazil (Tuberculose da val a e cervir-contribuicto à casulitica nacional) A brazil gin., 1945 10 1

The case of a negro woman of 34 years who had given birth to 7 full term children is here reported. It was one of the relatively rare instances of tuber culosis which attack the lemale sexual organs and one of the even rarer exemplars of the disease in which the attack was made on the cervix of the uterus. Finally it was one of the very rare cases in which the vulva was involved in the tuberculous ulcerative condition in fact the author states that this is the first instance of vulvar involvement to be reported in the medical literature of Brazil.

The patient visited the out patient department (medical division) of the Hornital Moncorvo Filho in Rio de Janeiro a year and 2 months after the birth of her last child complaining of physical and mental exhaustion and weakness, loss of weight and pains in the r gion of the lower abdomen which be came worse on exertion Physical examination at this time disclosed some disseminated subcrepitant rales in the chest but no evidence of any involve ment of the pelvic organs. A month later however the pa us had become worse, the patient entered the hospital and was assigned to the medical section, where a small amount of ascites was determined and a hemorrhagic liquid showing no trace of the Loch ha illus was asperated from the right pleural cavity l'aracentesis of the abdomen likewise yielded an ascitse fluid without trace of tubercle bacilli.

at the end of a months the effusions had cleared and the pains were gone however the vaginal discharge was very marked and the patient was sent the gynecological division. Here large irregular fixed masses were found on both sides of the cul-desac of Douglas and since one of these had begun to enlarge and soften the patient was transferred 15 days later t surgery where the intrapelvic process developed to the point where the uterus and other pelvic organs became enveloped in a single tumor

At laparotomy some time later 2 liters of caseous, purulent material rather fetid and of a yellowish green color were aspirated from the mass in the pelvis and a blopsy specimen was taken from the lining membrane of the pus pocket. On histological examination this specimen confirmed the suspected diagnosis of tuberculosis. No further surgical procedures appeared possible and the abdomen was closed

It appears that it was during this later period that there developed from the anterior lip of the cervix the indolent appearing ulcerative process with sharply punched out edges and sluggish lardacous foor which spread down the anterior wall of the vigina, and one patch about 34 Inch in diameter appeared on the internal aspect of the left labium major

Biopsy specimens from the vulva portlo vagualis, endometrium and endocervix disclosed (as depleted in excellent photomicrographs in the original article) the vascular characteristics lymphoid plasma, and Langhans cells as well as the scattered alcohol resistant bacilli of tuberculosis. The mycobacterium tuberculosis was cultured on Lovenstein medium and guinea pig inoculations proved positive

JOHN W BRENHAN M. D

#### MISCRLLANEOUS

Dujovich, A.: Elytrocele (Elitrocele) An. brasil gin. 1945, 10 116.

The elytrocele also variously known as vagunal hemia, enterocele vaginalis posterior Douglascele, prolapse of Froriep herma of the floor of the sac of Douglas, and colpocele posterior is rare but never theless more frequent than the anterior form of vaginal hernia. It is particularly important not to confound this condition with rectocele since a simple repair of the latter when accompanied by elytrocele, will usually result in recurrence. However other forms of defect of the pelvic floor usually accompany the elytrocele. It is well to be prepared to repair these at the same time.

The case history presented by the author was that of a woman of 55 years who had given birth to 3 children. Twenty nine years ago 4 years after the first accountement she had noted a protrusion of the vulva, which was painful on physical exertion. The

condition became gradually more pronounced until 19 years ago when she underwent a pelvic repair probably an anterior colporrhaphy and a colpoperi neorrhaphy—with relief for 4 years. Then the protrusion and other symptoms returned A pessary was worn for 7 years without relief and during the past 3 years the patient suffered from a sensation of heaviness in the vagina and on exertion a globular mass protruded from the vulva. The diagnosis at this time was genital prolapse colpocele, anterior cystocele, hypertrophic elongation of the uterine cervix colpocele rectocele and vaginal herma of the pouch of Douglas (enterocele)

At operation which was entirely vaginal, the anterior wall of the vagina, together with the cystocele was first repaired and the elongated cervix amoutated The incision was then carried around back of the cervical stump and the posterior surface of the latter was followed closely to guard against injury to the hernial sac. The sac, however was easily identified and freed up to its neck. When the sac was opened, it was found to be lined with the perstoneum of the pouch of Douglas and to contain a loop of the sigmoid colon. The sigmoid was pushed back through the neck a fingers in width which was then closed by a purse string suture with No I catgut and the sac itself was cut away. The closure was in turn reinforced by additional sutures includ ing the posterior surface of the cervix and the rectovaginal fascia on each side, which had been previously dissected loose from the posterior vaginal mucosa. The vaginal mucosa was then sutured with interrupted sutures of No a catgut to the posterior surface of the stump of the cervix, and the entire operation finished up with repair of the residual rectocele including the usual myorrhaphy of the levator muscles

It is now a month since the patient was operated upon although there is some shortening of the vagina she seems to be definitely cured. Indeed, the prognosis is generally good in these patients, provided that the condition be correctly recognized.

JOHN W BREDGIAN M.D.

### OBSTETRICS

### PREGNANCY AND ITS COMPLICATIONS

Dieckmann, W. J., Turner D. F. and Ruby B. A.; Diet Regulation and Controlled Weight in Pregnancy Am. J. Old., 1945 50 701

The pregnant patient must have a proper diet, but this does not mean that she should have an un limited calone intake and, as a result, gain excessively in weight. The pregnant patient does not have to eat for z of her own size. The diet must be in

creased during the last trimester

The necessary weight gain due to the physiological changes of prepancy—fettu, placents, ambotic dust uterus blood volume breasts—amounts to 67 kgm. Cheeley calculates from reports in the hiterature a gain of 6.a kgm. for the same physiological changes in pregnancy. There is no need for a total weight gain greater than 8 kgm. above the died weight. The first j months of pregnancy are characterized by either a little gain or a loss of weight. The swrape weight gain for the remainder should then be a maximum of 233 gm. (½ pound) per week.

Every patient whose total weight gain is over rook gm. does not necessarily have toxemia. Six tistles show however that the incidence of toxemia is increased in the patients who gain more than 13

If the patient a weight is ideal before pregnancy the maximum gain abould be between 7 and 8 kgm. A diet containing 1,800 calories is required. Enwarn L. Coavent, M.D.

### Lagercrantz, C. Electrophoretic Analysis of Serum in Pregnancy and in Pregnancy Toxamia. Upula lik form firk., 945 5 17

An analysis of serum proteins in pregnancy and in pregnancy toxemia has been carried out previously by gravimetric, nephelometric, refractometric, or precipitation methods. These methods have shown quite consistently that during preg neacy both the concentration of serum proteins and the albumin-dobulin ratio are lowered findings are more pronounced in toxemia, especially in cases in which there is much edema. Previous investigators assuming that the well recognized increased plasma volume of pregnancy is due largely to a plasma hydrema have suggested that the decreased protein content is in the main a dilution effect. Because this decrease in total protein is due solely to a lowered albumin they have regarded the unchanged value of the globulin as an expression of an absolute increase of this protein in the planua. In pregnancy toxemia where still lower albumin values are found it has been sug gested that these values are the result not only of further dilution but also of real loss of albumin. In the present study serum proteins were analyzed by

electrophoresis. The technique is carefully de-

Electrophoretic analysis was performed on serua from 16 narmal nonpregnant women, 9 normal programs women in the second to servant months of gestation 18 normal pregnant women in the last month of gestation, and 19 pregnant women in the last month of gestation with varying degrees of toormia. The analysis showed that

 The alpha and beta globulins increase both relatively and absolutely during normal pregnancy
 The albumin and total protein decrease during

normal pregnancy

3 Women with toxemia have a both relatively and absolutely larger alpha globulin than normal pregnant patients.

4. There is no significant difference in the electrophoretic patterns of umbilical cord serum after a normal pregnancy and after a toxemic one. Umbilical cord serum shows small amounts of alpha and beta elobulus.

The author correlates these results with previous work, although he makes no attempt to draw any

significant conclusions.

The alpha and beta globulins consist partly of lipids. It is known of course that in prepancy the serum lipids are elevated. The increase in these globulin fractions may be related to the lipems. In view of the small amounts of alpha and beta globulin found in the umbifical cond it is unlikely that the increase is caused by a transfer from the fetus

The molecular weight of both alpha and beta globulin is much higher than that of either albumin or gamma globulin. Consequently in tournis, when the permeability of the capillary walls may be pathologically increased, albumin and gamma globulin should leak through first and lead to a relative increase of alpha and beta globulin. The absolute increase, however must be explained by some other factor than filteration above

L. JAMES TALBOT, MLD

Co Junta Lateril and

Gimeno, A. M., and Orengo, F.; Capillaroscopy in the Toxemiss of Pregnancy with Special Refersures to Differential Diagnostic (i.e. capilaroscopis en les tovemiss de embarazo, con especial referencia al diagnostico differencial). Rev apra. etc., 947

3 2.

This is the conclusion of an article begun in the light issue of this same journal in which details of the technique and the criteria established by the au thors in judging the results of their observations will be found

The authors examined capillaroscopically 100 cases of toxemia, including 3 of chronic nephritis, 3 of vasculorenal disease, 22 of essential hypertension 47 of mild pre-eclampsia 17 of severe pre-eclampsia.

and 5 of celampaia. These capillaroscopic examina tions were made in the course of a broader investigation employing numerous other tests and methods of study such as blood pressures studies and studies of edema, of the effects of the administration of pitui tin and of congelation of the hematecrit findings of albuminuria and of sedimentation, and the results were correlated. When possible the observations were made both before and after delivery

Capillary architecture does not show sufficient modification to permit of differentiation between the mild and the severe pre-eclampsias. Acute nephritis is distinguished by marked anomalies of form such as undulation serpentine formation intercressing, anastomosis visibility of the subpapillar plerus of the blood vessels. There are no characteristic al terations in the picture of essential hypertension. In chronic nephritis and in vasculorenal disease deviations of form are, in the first instance scarce (undulation, some serpentine deformities and at times visibility of the subpapillar plexus). In the second condition there are even fewer abnormalities consisting solely of a certain amount of diminuition in the number of capillaries per field each vessel being somewhat narrower on the whole.

In general it is possible to demonstrate a relationship between the clinical picture and the capillary findings however incongruities are frequently present. The blood current in acute nephritis can show findings as poor as those in eclampsiz, and by the same token, much worse than those in chronic nephritis In cases of essential hypertension and in vasculorenal disease there is a persistent constriction of the vascular bed with changing blood current velocities and at times an accelerated or even

violent circulation

The postpartum capillaroscopic examinations result in two classifications the genume toxemiss (pre-eclampsis and eclampsis) and a group comprising all the other processes cited (chronic). In the list group the authors observe a total recuperation or at least a tendency toward recovery in the second an established condition with slight modifications persists. The value of a careful postpartum revision for substantiating the diagnoss is seen.

The authors consider capillaroscopy a diagnostic method, which sids in the differentiation between genuine toxenius and vascular disease or a chronic kidney condition especially when employed in the postpartum period. It also possesses a limited but evident value in prognosis and may serve as a guide in bringing out the effectiveness of therapeutic methods the authors having frequently observed the improvement with diet with magnesium sulfate and especially with hypertonic glucose solution. Juny W BELEGAM M.D.

Davis, L. J., and Forbes, W: Thiouracil in Pregnancy; Its Effect on the Fetal Thyroid Lancet, Lond, 1945, 249, 740

A case of mild thyrotoxicosis in a woman who was treated with thiourseil prior to and during preg nancy is presented. She died in the sixth month of pregnancy The cause of death was uncertain de-

spite autopsy examination

The thyroid gland of the fetus was enlarged and hyperactive, as compared with a presumably normal gland from a premature infant, and showed histological evidence of considerable functional activity It resembled the gland of an adult receiving too much thiouracil. It is suggested that thiouracil acts on the fetal phyroid after passing through the placents. The administration of thiouracil to pregnant women and probably to nursing mothers demands caution. George Edwards, M.D.

Beerman, H. and Ingraham, N R Jr : Recent Advances in the Management of the Syphilitic Pregnant Woman Med. Clis N America, 1945 29 1463

There is now general agreement that syphilis is exclusively transmitted to the fetus by the mother Most evidence shows that the fetus is infected in the later months of pregnancy and not shortly after conception.

Routine blood testing in prenatal patients becomes a matter of great importance because op per cent of the women are unaware of their infections. In the expenence of the authors there is no evidence that pregnancy impairs the sensitivity or specificity of the tests.

In the treatment, drugs with a strong spirillicidal action must be used These are necastiplicamina, arxenoxide and periodilin. Bismuth and mercury alone are not effectual. An outline for the use of these drugs is given, with the greatest discussion being devoted to peniciliin. Treatment began at the fourth month of pregnancy and continued at weekly intervals to total not less than 4 gm. of necarphens mine, or the equivalent of arsenoxide with or with out bismuth subsalicylate. Pregnant women tolerate arsenical and heavy metal treatment well but a urine examination and blood pressure determina tion before each treatment is important.

Penicillin therapy is the same as for the nonpregnant adult. The spirochaeta pallids was seidom found in the open lesions longer than 12 hours, and the lesion itself was completely healed in I week. The therapeutic shock at the beginning of treatment may be harmful to the fetus. A large percentage of the women develop abdomind pain, gastromestinal disturbances and on several occasions presented symptoms of threatened abortion. For this reason the initial dose is reduced for the first 48 hours. A total dosage of either 1,200,000 or 2,400,000 Orford units of sodium penicillin is astificatory both to prevent infection of the fetus and to cure the duesae in the mother. This total dosage is given intramuscularly 2000 outils every 3 hours with a reduction during the first 8 hours. The total treatment course takes 8 or 9 days.

Twenty-seven of the women treated at the University of Pennsylvania Hospital Philadelphia have thus far been delivered and their babies followed up

for periods which vary from a months to a year with no evidence of syphilis

CATHERINE B HEPL M.D.

# LABOR AND ITS COMPLICATIONS

Resnick, L.: Spinal Analgesia in Operative Obstet rica Brit. M J 1945 2 7 2

Although the safety of spinal anesthesia for ceneral surgery has been generally accepted, its use in obstetrics is still considered dangerous. The author reports a series of 137 cesarean sections and 256 operative vaginal deliveries done under heavy nu percain (1 in 200 in 6% glucose in 3 c.c. ampules) spinal anesthesia.

Premedication was given to all women who were to be delivered by cesarean sections it consisted of omnonon gr 1/3 and scopolamine gr 1/300, given about 45 minutes before operation, and in addition, atropine at 1/100 and ephedrine at 1 for varinal deliveries most of them had had some premedication during the labor but were given cubedrine or 1

The dosage for cesarean sections varied from 1.2 to I 5 C.C. of the solution and for vaginal deliveries from o 5 to 0.5 c.c., which gave anesthesia to lust

below the umbilious.

The indications for and the types of cesarean section performed are summarized 75 per cent of the sections were of the lower segment type. Of the 2x6 vaginal deliveries 136 were made by means of the outlet forceps, 108 by midforceps, 8 by high forceps, 6 by breech extraction, and 4 by craniotomy Rotation of the head was performed 167 times

No maternal deaths occurred in the cesarean group, while a of the patients delivered from below died (one because of pulmonary embolus and the other following sulfonamide therapy for pyelitis) in neither case was the anesthesia responsible for the death. Seven (5%) of the cesarean babies and 34 (13%) of those delivered from below died but none of these deaths could be attributed to the anesthesia.

The author considers the following to be the advantages of spinal anesthesia

# For the mother

- I It is safe when inhalation anesthesia is contra indicated.
- 2 It is safe in pre-eclampsia and eclampsia. It is safe in essential hypertension.
- 4 Uterine atony and hemorrhage are rare
- 6 Pulmonary complications are rare. 7 Postoperative discomfort is absent.

# For the physician

The technique of its use is simple

- It may be used when skilled anesthetists are not avallable.
- 3 It affords maximal relaxation of the pelvic muscles.
- 4. No additional anesthesia is needed for repairs.

- The contraindications to spinal anesthesis are t Cases in which the central nervous system or
- spinal disease interferes with aseptic technique. 2 Abnormal presentations
- 3 Blood pressure below 100 mm. of mercury A Acute shock.
  - Acute beart fallure Constriction ring dystocia

#### NEWHODN

Wiswell, G. B.; Anemias of the Newborn, Cond. M Au J 1945 53 555-

Anomia is defined as any state in which the hemoglobin is less than normal in proportion to the blood volume. This state can arise from several cames such as blood loss, failure of cell formation or bemoglobin, excessive cell destruction or combinations of these.

These anemias are reviewed under four headings Anemia due to kemorrhage Hemorrhage may be suspected if the red cells drop to 4,000,000 with a corresponding reduction in hemoglobin. It is a hypochromic type becoming microcytic if the loss continues. Nucleated red blood cells appear and the reticulocytes increase. The leucocytes increase to from ro,000 to 30,000 and the platelet count is normal or raised

Traumatic hemorrhage usually occurs in the first two days and may be severe enough to cause anemia.

The two most common diseases of the newborn

giving rise to spontaneous bemorrhage are Hemophilia which is rare. The clotting time may be prolonged for hours but the blood eventually clots. Treatment consists of frequent transfusions.

Hypoprothrombinemia. This is very important and takes the form of constant ooring. It usually appears between the second and eighth day Marked increase in the prothrombin time alone characterizes Vitamin K administration to the this condition mother in labor or intramuscular injection of the newborn is remarkably efficacious in preventing of

benefiting this condition. Anemia of infection The hematopoletic systems of babies vary in their vulnerability to infection Anemia lowers the resistance to infection and infec tion aggravates the anemia. Severe pyogenic infec tions, septicemia pyelonephritis, and pneumonis may cause a serious drop in hemoglobin. Streptococcal and bacillus coll infections are more likely to cause anemia than streptococcal infections although a hemolytic staphylococcus may cause severe anemia

even of an aplastic type. Congenital syphilis is the chief offender of the

chronic injections. Acute congenital hemolytic anemia may rarely

follow infection and sickle cell anemia, occurring only in negroes, may be precipitated by infection. Repeated transfusion is the treatment of choice

and if the anemia persists there has probably been some destruction of the bone marrow

Anomia of prematurity This type is characteristic of all immature infants and its severity is governed by the state of maturity. The anemia may not reach its maximum for from 8 to 10 weeks and at 2 months a gradual improvement sets in. Various workers have shown that iron is not directly involved in the causation of this anemia. Immaturity of the hemopoletic system makes it difficult for these infants to perform postnatal adjustments and to recover the normal volume of blood and its constituents.

In the early stages it is a normocytic normochromic anemia. Microcytosis occurs later The

prothrombin time is often increased

These babies are potential bleeders and they require vitamin K more urgently than normal infants. Treatment with iron is of some use only after the third month at which time there is a natural spon taneous tendency toward recovery Transfusion has only a transitory effect and is used only to combat infection and complications.

Anemias due to hemolysis These are for the most

part related to the Rh factor and its workings. The author gives a good review of the mechanism by which Rh incompatibilites cause hemolysis of the blood cells in infants and subsequent anemias. The hemoglobin may fall to 20 per cent and the red blood cells to 1,000 000 The treatment is multiple transfusions of Rh negative blood.

Tompkins P : The Timing of Ovulation with Basal Temperature Graphs Med Clin. N America 1945 19 1415

Graphs of the daily basal body temperature have been used by the author as an index to ovulation in cases of sterility Special graph paper or improvised paper is suitable. The patient is instructed to take her temperature rectally with an ordinary clinical thermometer each morning upon awakening and before rising drinking eating and smoking. It is to be recorded if any acute infection exists at the same time although marked upper respiratory in fections produced practically no change in the rectal temperature The results of this method concur with the established theory that ovulation occurs on the fourteenth day before the menstrual period regard less of the intervals of the periods.

The time of ovulation is marked by a rise in rectal temperature, which is sustained for several days and is usually preceded by a slight fall in tempera ture. If intercourse occurs near the time of the temperature shift there will be a better chance of conception than if intercourse occurs only at other times in the cycle. The span during which the ovum is susceptible to fertilization is believed to be from 12 to 24 hours The author states that the length of pregnancy is 266 days rather than the accepted 280 days.

The reason for the temperature shift is not established Two suggestions are offered (1) that progesterone elevates the temperature and (2) that during the preovulatory phase the temperature is

depressed by estrogens.

The basal body temperature graphs can be used for the following (1) to determine the time of man mum and minimum fertility (2) to determine the time for artificial insemination and endometrial biopsies (3) to aid in securing early human ova (4) to help in evaluating the effectiveness of treat ment designed to produce ovulation, especially x ray therapy and (s) in occasional cases to predict the date of delivery CATHERDOR B HESS, M.D.

for periods which vary from a months to a year with no evidence of syphilis,

## LABOR AND ITS COMPLICATIONS

Resnick, L.: Spinsi Analgesia in Operative Obstet rics. Brit. M J 1045 2 722.

Although the safety of spinal anesthesia for gen eral surgery has been generally accepted its use in obstetrics is still considered dangerous. The author reports a series of 137 cesarean sections and 256 operative vaginal deliveries done under heavy nu percain (1 in 200 in 6% glucose in 3 c.c. ampules) spinal anesthesia.

Premedication was given to all women who were to be delivered by cessrean sections it consisted of omnopon gr 1/3 and scopolamine gr 1/300, given about 45 minutes before operation and in addition, atropine gr 1/100 and ephedrine gr 1 for waginal deliveries most of them had had some premedication during the labor but were given ephedrine gr 1

The dosage for cesarcan sections varied from 1 s to 1 5 c.c. of the solution and for vaginal deliveries from 0.5 to 0.8 c.c. which gave anesthesia to just

below the umbilicus.

The indications for and the types of coverean section performed are summarised 75 per cent of the sections were of the lower segment type. Of the \$56 vaginal deliveries 136 were made by means of the outlet forceps 103 by midforceps, 5 by high forceps, 6 by breech extraction and 4 by craniotomy Rotation of the bead was performed 167 times,

No maternal deaths occurred in the cesarean group, while s of the patients delivered from below died (one because of pulmonary embolus and the other following sulfonamide therapy for pyelltis) in pelther case was the anesthesia responsible for the death. Seven (5%) of the cesarean bables and 34 (13%) of those delivered from below died, but none of these deaths could be attributed to the

The author considers the following to be the advantages of spinal anesthesia

#### For the mother

- I It is safe when inhalation anesthesia is contra indicated.
- 2 It is rafe in pre-eclampsia and eclampsia.
- It is safe in essential hypertension. 4. Uterine atony and hemorrhage are rare.
- Obstetric abook is rare.
- o Pulmonary complications are rare.
- 7 Postoperative discomfort is absent.

# For the physician

- The technique of its use is simple. It may be used when skilled anesthetists are not
- 3 It affords maximal relaxation of the pelvic
- No additional anesthesia is needed for repairs.
- muscles.

- The contraindications to spinal anesthesia are r Cases in which the central nervous system or
- spinal disease interferes with aseptic technique. 2 Abnormal presentations.
- Blood pressure below 100 mm, of mercury
- Acute shock.
- Acute heart fallure.
- Constriction ring dystocia.

#### NEWBORN

Wiswell, G B.: Anemias of the Newborn, Canal. M Am J 1945 531 555.

Anemia is defined as any state in which the bemoglobin is less than normal in proportion to the blood volume. This state can arise from several causes such as blood loss, failure of cell formation or hemoglobin, excessive cell destruction, or combinations of these.

These anemias are reviewed under four headings Anemia due to hemorrhage Hemorrhage may be suspected if the red cells drop to 4,000,000 with a corresponding reduction in hemoglobin. It is a hypochromic type becoming microcytic if the loss continues. Nucleated red blood cells appear and the reticulocytes increase. The leucocytes increase to from 20,000 to 30,000 and the platelet count is normal or raised

Traumatic hemorrhage usually occurs in the first two days and may be severe enough to cause anemia. The two most common diseases of the newborn

giving rise to spontaneous hemorrhage are

# GENITOURINARY SURGERY

## ADRENAL KIDNEY AND URETER

Peters, J T : Origin and Development of a New Therapy for Grush Injury Transfusion Kidney and a Certain Number of Other Diseases, Ads mai. reset 1945 123 90.

Considering the fact that a part of the kidney function is a mechanical filtration process the author constructed an artificial nephron of glass and rubber By means of this apparatus it could easily be demonstrated that not only oligoria and anuris but also polyruis could be indisted by a purely mechanical device. The indication annuts was produced without any obstruction, as a result of increased intrarenal pressure which caused a decrease of the effective filtration pressure

The presence of an increased intrarenal pressure in vivo is readily deduced from certain pathological facilities. Thus the obstruction of the tubeles by blood clots, cell detrims and crystals is often found at antopay to be present only in a small part of the kidney or it is altogether absent. An obstruction, therefore is unnecessary for the development of anumia.

In mercury poisoning crosh injury transfusion kidney and several other diseases oligaria or sauria sanciated with hyperactorna and uremia is the important syndrome. For the treatment of these conditions, decapsulation of the kidney is recommended, on the assumption that the condition is the result of increased intrarenal pressure. This should be considered an emergency operation, and should be done on the fairt day that the syndrome develops

Uremis caused by glomerular destruction, how were must be sharply differentiated from the uremia caused by increased intravenal pressure. The former cannot be cured by lowering the intravenal pressure by a few millimeters of mercury. In the latter decapsulation, distreties and pressor drugs are now whichy used either separately or in combination, and apparently with success. Success Kaser M.D.

Abramson, D. J.: Renal Typhoid Fever; Presentation of a Case of the Primary Type, J. Urel. Balt., 945-54-452.

A case of primary renal typhoid is presented. It is of additional interest because of the presence of calculf and pyclonephrous. Enteric typhoid had been consistently excluded by negative clinical finding, Widsi tests, and stool and blood cultures.

Emphasis is placed on the necessity of careful bac teriological examinations of routine urmany cultures, the lack of significance of Widal tests in previously immunised individuals and the value of conservative treatment. The role of sulfonamides in renal typhold deserves further study

Both primary and accordary renal typhoid are discussed. The epidemiological significance of ty phold disease of the kidney and of the carrier state is emphasized Joen A. Lozz M.D

Jacoba, A.: Tuberculous Disease of the Kidney Glarges M J 1945, 144: 161

The author presents a set of concepts for dealing with tuberculous disease of the kidney based on a series of over 350 nephrectomies and a further natotated series of nonperated cases of renal tuberculosis. He divides the disease into three main clinical groups tubercle bacillaria without urfurny symptoms renal involvement with signs and symptoms confined solely to the urfuracy tract and no other colorious tuberculous focus and renal involvement appearing subsequent to the occurrence of an extra renal larlow.

Tubercle bacilluria according to the author requires only follow-up urtological camination. In many cases the minute renal lesions accounting for the bacilluria will heal, in others, the microscopic foot will progress and the accord clinical condition will develop that of obvious renal involvement in unlitateral disease nephractomy is lodicated. In bilateral involvement the operation is contradiated unless the involvement on one side is minimal and it is believed that removal of the badly infected kidney will materially improve the patient agencial condition. In cases of renal toberculosis complicated by extravenal foci the more serious life taking lesions are greated precedence in the institution of treatment.

Intractable tuberculous cystitis, which has failed to show improvement over a reasonable period of time following nephrectomy will require diversion of the urinary stream by pephrostomy cutaneous arcterostomy or transplantation of the ureter into the bowel.

CLARDER V HOGGER, M.D.

Ladewig, P., and Eser S : Malignant Tubular Adenoma in a Horseshoe Kidney; Ita Significance with Regard to General Cancer Pathology J P li. Bad Lond., 945, 37 495

A case of malignant tubular adenoma arhing within a borschee kidney in described by the au thors and discussed with regard to fits bearing or general cancer pathology. It is concluded (i) that the tubular adenoma coght to be regarded as ancer matrix according to Cohnheim's theory of displaced embryonic tissue. (s) that such displaced embryonic tissue (s) that such displaced embryonic tissue as well as hyper regenerative hormonal and other tissue disturbances merely provide zones of potential growth teatability (3) that in these zones. Irritation in the widest conception of the term may induce the fatal event of the cancer cell s birth as a somatic mutatlom and (4) that Cohnheims theory and the irritation" theory of cancer are not mutually exclusive but complementary

The most widely accepted view is to regard the tubular adenoma as the result of an abnormality in fetal development at the time when the ureteric bud joins up with the metanephrogenic blastema and induces its differentiation and growth. In this stage certain elements of the tissues involved may fail to establish contact and become excluded from the co-ordination of further development. They are left free to unfold their remaining growth potency in unusual ways. This theory finds support in the authors case from the peculiar combination of adenoma and horseshoe kidney. It is in fact generally agreed that horseshoe kidney is due to unusual growth impulses of the metanephrogenic tosues whereby the bilateral blastemas come into collision. In view of this the authors believe that they can accept the dysontogenetic nature of the tubular adenoma.

The tubular adenoma with its dysontogenetic origin is only a peculiar ground on which the malig nant change has taken place. In the same way adenoma of the currhotic liver predisposes to malig nancy as do adenoma of the prostate certain forms of adenoma of the female breast and in rare mstances adenoma of the thyroid gland. The cause of the formation of these different adenomas is the potentiality for prospective growth in existent embryonic tissue hyper regenerative power in impaired tissue or even unbalanced hormonal atimulation. But none of these can be regarded by themselves as responsible for the induction of malignancy This is shown by the uneven ratio between the frequent occurrence of adenomas and the relatively rare incidence of their malignant transformation. Moreover, in accordance with recent research on the subject we are justified in assuming that spontaneous cancer development is the result of an incidental and peculiar combination of various factors and influences no one of which necessarily bears directly and specifically on the final result. JOSEPH K. NABAT M D

Bowle C. F., and Bors, E.: Primary Carcinoma of the Ureter J Urol Balt. 1945 54 434-

Primary carcinoma of the ureter can still be considered a rare tumor although an increasing number of cases have been reported during the past decade. The total number of reported cases up to date is 175.

A case of carculoms of the areter complicated by conflicting the reported of the operative technique is reported. The operative technique is reported in detail because certain well recognized general surgical principles used in attacking malignant tumors anywhere else in the body were employed. No prionty is claimed on the technique.

The principles carried out in this case were (1) opening of the pentioneal cavity for evidence of spread of the tumor (2) beginning dissection in healthy tissue above the tumor and (3) after the tumor was reached from above, dissection on the bladder side with the electrosurgical knife the whole

tumor being removed en masse. The kidney and remaining portion of the ureter were removed 4 months later. No evidence of tumor was present Cystoscopy revealed a normal bladder with no evidence of recurrence.

JOHN E. KIRKPATRICK M.D.

# BLADDER, URETHRA, AND PENIS

Krafka, J Jr: The Elasticity of the Human Uri nary Bladder J Urol Balt. 1945 54 438

Incidental to studies made on the elasticity of the human aorta tests were run on the elongation of standard strips of urinary bladder. The technique used was that previously described in which in creating weights applied by the gravity pull on a carriage running on an inclined plane, exert a stretch ing force on the specimen and automatically record the relationships. The machine used was the Scott serigraph, which is commonly employed in fabric laboratories for measuring the elasticity and the tensile strength of thread

It is common textbook knowledge that the detru sor serves as the principal agent in the emptying of the bladder. The urologuets are also aware of the character of the pressure curves developed during the filling of the bladder. The commonly accepted value for emptying of the bladder is between 20 and 40 mm.Hg upon which is superimposed an addi tional volitional pressure produced by contractions of the abdominal muscles and the descent of the dia phragm which brings the total intravesicular pressure to approximately 74 mm. It is also observed that the pressure developed upon the addition of successive increments of fluid to the bladder volume is initially high but immediately levels off to fixed values proportional to the volumes prevailing. These reactions are commonly interpreted as due to balance in muscle tonus and the primary and secondary pressures are used as indications of hypertonicity or atony in various pathological states.

That such pressures prevail at other sites in the body has been well established Hamilton. Wood bury, and Harper (1936) have made a study of cough and strain upon the blood pressure and upon the cerebrospund fluid. Intracranial pressure may be raised so mm Hag and there is one record of a blood pressure of 380 mm, due to strain.

Woodbury Hamilton and Torpin (1937) in an analysis of intrauterine pressure have shown that 70 mm. pressure can be transmitted to the intragss tric pressure and a like equivalent to the pregnant uterus.

Muschat (1935) noted a maximum of 60 mm Hg
pressure in the bladder of the tabetic with a para
lyzed bladder wall but an lytest abdomes

pressive in the bladder of the tabelic with a para lyzed bladder wall, but an intact abdomen. Another concept, of course would need to be con sidered in a corollary to the one just developed namely the protection of the unterpracing the

sidered in a corollary to the one just developed namely the protection of the ureters against these high intravesicular pressures. Wuellenweber has made a study of the pressure prevailing in the kidneypelvis at various intravesicular pressures. The for mer is always lower than the latter. Thus at 120 mm, bladder pressure the pelve pressure is 70 mm (water) at 350 it is 200 mm. This factor however is not so significant as the main one alone the angulation of the ureter and the muscles of Waldeyer seem to provide a competent mechanism to prevent transmissal of the high pressures to the ureter.

That the musculature of the bladder does main tain a definite tome is acen in the work of Holmes (1933) on the paralyzed bladder. Injury to the cervical, dorsal, or sacral cord results in an atomic bladder with a characteristic volume pressure re lation on filling. His figure 2 shows a deninte filling emptying curve which are reciprocals. His figure 2 shows one of the features noted by Laugnorthy namely a thany straight line rise followed by a rapid return to a base line in the course of a few minutes.

The effective stimulus to the emptying of the bladder is commonly assumed to be tension in the bladder wall. Free nerve endings and pressure corpuscles have been described, but it is difficult to see how these can in one instance give the sensation of fullness then urgency and lastly pain. If the simple assumption is made that the tonus of the muscle develops and mediates the semation a rea sonable opinion is at hand. Hypertonic bladders empty at small volumes atonic bladders store tremendous volumes of urine either under pathological states or in the last months of pregnancy | Irregular contractures are seen normally at 400 c.c. volume and spontaneous contractures are noted after the steep parts of the cystometrogram curve. Curves are materially affected in the case of megacolon. How these factors could be applied to simple nerve end ings of to pressure corpuscles is not clear but they would all be effective in muscle tone. Smooth muscle must act as a sensory ending to mediate its own reflexes either local or central

The percentage stretch of standard strips of unnary bladder have been measured and Young's modulus calculated. The values range from 0.488 to 4.840 dynes per centimeter square x to<sup>4</sup>

The classicity curves for the bladder have been compared to those for the aorta. The character of the curves is essentially different that for the aorta is a geometric curve, for the bladder a straight line curve. Within the limits of the test, the distensibility of the bladder is not checked by collagenous fibers such as are seen in the aorta.

Calculations are presented which equilibrate the atretching forces against manometric pressures as noted in the bladder by other investigators using the cystometer

The theory of muscle function in the bladder is discussed. The primary function of bladder empty ing for the detruour as accepted. Secondary functions are 3 in number. The first of these is to provide an elastic membrane which can adjust bladder volume to bladder pressure. The second function is to provide a local elastic mechanism to adjust of the accessory pressures impressed on the bladder by cough and sirato. The bladder considers the muscle as

a sensory organ for the mediation of the stress sense as a attinuous to voiding Jone E. Kirkentrick, M.D.

#### GENITAL ORGANS

Heyman, A., Beeson, P. B. and Sheldon, W. II.; The Diagnosis of Chancrold. J. Am. H. Att., 1945, 179, 935

The methods employed at present for the diagnosis of chancold are far from satisfactory. Current carbooks Indicate that accurate diagnosis can be based on the clinical features on the results of attness, or on the camination of stained smears. Most venereologists, however know that each of these methods is subject to major indications and errors. Actually at present the diagnosis is usually based on negative dark field caminations for spirochets, and on clinical improvement after the institution of sul consmide therapy. The establishment of reliable criteria for a positive diagnosis of chancrold would impressionable be of value.

The present article is a report on the relative efficiency and usefulness of a number of diagnostic procedures in chancroid. These findings were obtained during an intensive study of a group of 125 patients suspected of having either chancroid or trumboursulous venerum.

Appositive dagnoss of chancool was made in to of them. Of the various methods, blopy appears to be the mort efficient single method of diagnoss and can be depended on to give a diagnosis in over 10 per cent of the cases in which it is applicable. Its use is limited to cases in which there are primary gmittal lesions. The removal of tissue for biopsy is in most materies as simple procedure, well suited to out patient work. It is undestrable however in patients with small telesions because of the pain involved.

Cultural demonstration of the Ducrey bedills can be accomplished in at least 15 per cent of all cases. The technique is not difficult and can be carried out by a competent technician. Culture is less likely be successful in advance! Issions which are heavily contaminated with other bacteria. It is the commeans of obtaining a positive diagnosis in patients

with buboes but without primary lesions. Diagnosis by means of direct amears of genital lesions is possible in approximately 50 per cent of the cases. This method has the advantage of simplicity and immediate of diagnosis. Unfortunately, it is likely to be useless in advanced lesions, in which there is a beay y growth of other bacteria.

Autoinoculation has several disadvantages and does not take with sufficient frequency to make it of

value in routine work.

The skin test for chancrood should never be relief on as the sole method of diagnosts although it may be of limited value as an adjuvant to other procdures. In this group of 6e proved cases of chancrold, positive skin tests were found in only 46 (77 per cent). A further disadvantage lies in the fact that a positive skin reaction persists for many years elter an infection and therefore may not be significant in

The diagnosis of chancroid can in the majority of reference to the present illness cases be established by suitable laboratory pro-

# Lazarus, J A.: The Significance of Spontaneous Hematuria Associated with Hypertrophy of the

Prostate J Urol. Balt. 1945 54 531

Spontaneous hematuria is not infrequently an outstanding symptom among patients, with pros tatism and in certain instances it may be the chief complaint. The hematura may vary from the companie. And memacuna may year mon mer presence of a few crythrocytes to the high power held (occult blood) to massive bleeding which may at times assume slarming proportions due to the prostate itself or to conditions which are extrinsic to the prostate, such as a cystitis secondary to and aggravated by urinary retention vesical renal, and ureteral calculi tumors of the bladder or in vesical diverticula tumors of the kidney hy dromphrous and scute or chronic glomerulone

Since the hematuria is due so commonly to the prostate itself the urologist is frequently too casual in his examination after establishing the presence of phritis a protestic hypertrophy If he then proceeds to reform a prostatectomy under the mistaken notion that the bleeding is due to the prostate, when in reality it is due to a coexisting renal tumor or so ne other condition which is unrelated to the prostate

The author is therefore, of the opinion that a the outcome may be disastrous. complete urological study is indicated in every case

of prostatic hypertrophy with hematura. Although many urologists have citablished an aversion for one reason or another to performing cystoscopic examinations upon their prostatic patients the author believes that cystoscopy should be carried out in these cases whenever it is tech nically possible. He believes that the cystogram and other indurect methods give madequate information In addition to providing direct visualization of the region to providing direct visualization of op-veilcal neck and lumen, cystoscopy gives the op-portunity to catheterize the ureters and to take retrograde pyelograms in the event that no obvious cause for the bleeding can be found in the bladder or

FREDERICK LIEBERTHAL, M.D. in the prostatic urethra.

# Ferguson J D and Pagel W Some Observations Buson J D and Page! W : Some Unservations on Cardinoma of the Prostate Treated with Eartogens, as Demonstrated by Serial Biopsies.

The authors carned out repeated biopsies by transurethral resection in a small number of patients with cardnons of the prostate who had received the testrogens for from 6 to 30 months. They datin with carcinoma of the prostate who may receive the carrogers for from 6 to 30 months. They distinguish two types of tumors those which arise in attrophic thems to the carrocket take of an otherwise attrophic thems to the carrocket take of an otherwise attrophic thems. two types of rumors mose white all the control of t normal gland and those which develop secondarily in a gland presenting benign hypertrophy

latter are usually latent and are discovered during routine microscopy of the enucleated gland. The former are more common, and have usually extended by the time the diagnosis is made. All of the ma

tenal studied was composed of this type.

The authors took a careful history studied the rine aurinors cook a careful majory angued me urine for infection, tested renal function and repeatedly estimated the serum acid phosphatase. Anteroposterior views of the lumbar spline, pelvis, and upper ends of the femura were taken before and Occasionally intravenous urosucer made. Four of the 5 cases were treated with stilbestrol and I was treated with dienestrol after treatment. The Gershom Thompson cold punch was used and biopsy specimens were taken from the posterior quadrant of the prostatic urethra immediately above duscussus of the president and manufacture and the vertimentanum Coagulation hemostasis was

The studies showed that in addition to an apused as infrequently as possible, and shudad showed that he southern to an appearant reduction in the number of tumor units in the later sections there were cellular changes such as a diminution in the size of the nuclei measured quantitatively There was a regressive change from more cellular type of growth to a scirrhous form. In later sections there was again a diminution in the size of the cell nuclei with concentration of chromatin pyknosis and vacuolation of the cells DAVID ROSENSLOOM, M.D.

# Muschnt M : Osteltis Publs following Prostatectomy J Urol., Balt., 1945 54 447

The condition described is rather unusual. It was hist presented as an entity by Beer in 1924. Since urse presented as an entry of the first presented as an extensive of them an occasional report is found under the title of periostitis osteitis publs or osteochondritts depending on which thate seems predominately af rected Osterlis publs appears as a distinct disease entry with a more or less characteristic course entity with a more of the contract to the cont tuberculous osteomyelitis. It occurs in a small num ber of patients following operations upon the urnary ber of patients 1010wing operations upon the urnary bladder especially after prostatectomy. It is an inhammatory process of the bone which begins in the amount of the bone which begins in the support of the bone which begins in the the symphysis pubis and gradually involves the one sympays pure and gradually involves the multi-rami all the way down to one or both ischill this inflammatory process spreads via the perior this inflammatory process. teum to the variously attached muscles of the pelvis equal to the various and levator and expectably the obturator internus and levator and keeping them in a spastic state Aschner describes keeping them in a spasue state Ascaner describes the characteristic clinical picture most graphically. The pain is intense and disabiling in its effects. It

forces the sufferer to lie down and when down he cannot get up nor turn from side to side, except in

The chology of this condition is obscure the The ethology of this condition is obscure the clinical picture with its symptomatology however is clear and follows a definite pattern. This pattern is clear and follows a fear and agony is practically identical in every case from the onset is practicently securious in visity base around the patient of the disease until clinical cure ensures the patient of the casesse until cunical cure ensures the patient going through a period of physical agony lasting from \$10 12 months Two cases of ostellis publis are from \$10 12 months Two cases of ostellis publis are from 3 to 12 mounts and a summary of the lew cases from the literature with a discussion of the etiology symptomatology clinical findings, x ray studies pathology therapy and prognosis, is also included

As in every other disease in which the sufferings of the patient are very great and prolonged various therapeutic agents were tried. The most frequently used therapy was disthermy baking and massage. Note of these therapeutic procedures beloed in the slightest. Most patients claimed that the dathermy aggravated their patients claimed that the dathermy aggravated beit patients. Any therapy was found uscless Application of a body cast is always suggested by the orthopedic surgeon who believes, and rightly so that immobilization of the pelvid by a solid body cast will relieve the agony of pain. The patients however are very intelerant to a body cast.

It is the author's conviction that the disease is self limited and that surgical intervention is not required but if an abscess does develop it should of course be properly drained Penicillin (4,000,000 units) was used in case a without any subjective improvement whatsoever but it may have caused the absorption of the inflammatory lumps near the uchii. Sulfa drugs were tried without influencing the condition one lots. Any manipulative procedure to hasten the recovery is strongly contraindicated it only aggravates the condition and stirs up local traums, thus actually spreading the disease process and delaying the recovery. In a case reported by Barnes the patient submitted to the "adjustments" of a chiropractor for several months. The adjust ments were usually followed by chills and tempers ture as high as 105, and the patient was told that these reactions were supposed to be very beneficial. The majority of patients become so apprehensive that before long one gets the impression that they are greatly exaggerating their pain. The physician therefore, is frequently tempted to force early ac tivity and to encourage the patient to get out of bed and move about. The author found such forceful actions detrimental to ultimate recovery which was retarded for many weeks. He states that "whenever such activity is contemplated another x ray study will usually disclose that instead of improvement the process is at its worst and absolute rest is indicated

Proposis The ultimate outcome in all cases is good There is no spread of the disease to other structures or organs. The only complication is an occasional aboves formation with restitution after diainage. The only demonstrable sear is the complete outlieration and ankylosis of the symphysis. This, fortunately remains symptomicss and the patient resumes his normal life.

JOHN E. KIRKIMTEICK, M.D.

Bishop, P. M. F. i Studies in Clinical Endocrinology. The Management of the Undescended Testicle. Gey'. Herp. Rep. Lond., 1945. 94. 12.

The author emphasizes the importance of close co-operation between the endocrinologist and the surgeo in deciding which form or combination of forms of treatment of undescended testicle will be most effective and states that the decision should be based upon the individual situation present in each case. In his terminology the word testicle" is used in its literal sense, i.e., a little testis. He describes the mechanism of normal testicular descent as or curring in three stages - shdominal canalicular and extracanalicular - and extensively reviews the literature to discuss the various causes that have been postulated to account for incomplete descent. These are fetal peritonitis defective development of the transversalis fascia intercolumnar fascia, cremasteric fascia or muscle abortening of the cremaster muscle because of too powerful contraction, short ening of the processus vaginalis or of the cord structures, absence of the external ring and absence of the entire inguinal canal including both internal and external rings. Maldescent is often found to be associated with other physical and mental consenital deformities. The incidence of various positions of arrest, as described by various observers, is dis-CHECK!

Apart from the mechanical factors tocklent to body growth that play a role in the normal deserts of the testicle, chorisoing consideration is responsible endocrine factor. It causes enlargement of the testicle (inclinetty a mechanical factor) stimulates the development of all the connective tissue elements associated with the testicle in its descent, and therefore elongates the cord structures and, by its action on the intertitidal tissue of the testicle stimulates the secretion of androgen which "secondarily causes full development of the sexual apparatus, the assisting the descent of the testicle" (Molen, d Ymour and Gustavam quoted by the author)

d Immor and Giniaryon quoted by the author). A portion of the author's cases support the some what controversial view that androgenesis is if lected by maddeacent the author is in full agreement with other writers that spermatogenesis is producedly affected. He also believes that choosing gonadotropin, although it may attendate androgenesis has no effect on spermatogenesis.

The evidence both direct and indirect, for spon taneous descent of the testicle after birth is reviewed

with the conclusion that it does occur Complications and sequelae incident to an descended testicle are pain, vulnerability to traums, infection, hydrocete torsion synchological effects and malignant degeneration. However endocrine or surgical procedures for inducing descent do not seem to diminish the possibility of mailignancy

From a surgical point of view cases may be

classified into three groups

Surgery of the atrophied terticle i.e., removal to prevent possible malignant changes orchidopsy for commetic and psychological reasons or either procedure to avoid the liability of traums or tornion. Surgery of the testicle with a deviated or impected

Surgery of the testicle with a deviated or impeded descent, in which the problem is porely a mechanical one and consists merely of obvisting the difficulty caused by fibrous bands adhesions, or bernial in rolvement. The best surgical results are obtained in this group subject to the author's arbitrary quali fication that the patient should not be older than 10 or 11 years

Surgery of the testicle with a delayed descent which is rendered difficult by the problem of pre-

serving the blood supply of the testis

The optimal age for endocrine therapy must be determined because (1) overdosage at an early age may lead to premature puberty (2) the tissues are more responsive at the time of puberty and (3) the longer a testicle is left undescended after spermatogenesis begins, the greater the danger of irreparable damage first to the seminiferous tubules and later to the interstitial tissues. The criterion for dosage is the tendency toward excessive androgenic de velopment. Most authors cited believe that endocrine therapy should not be continued for more than a few months. Abdominal testicles are not likely to respond to endocrine therapy canalicular testicles are more responsive in a high percentage of cases (60 per cent in the cases cited by the author) and extra canalicular testicles are difficult to evaluate and are therefore excluded from the author's analysis Ad verse effects of endocrine therapy employed in proper dosage were not noted by the author

The conclusions derived from this study are (1) the extracanalicular testicle is a surgical problem (2) the canalicular testicle is primarily an endocrine problem and should be treated surgically only after endocrine therapy has falled or when there is a complicating mechanical impedance and (3) the abdominal testicle is unlikely to respond to either method of treatment.

CLARKET V HORODE, M.D.

Vermeulen C. W and Hagerty C. S: Torsion of the Appendix Testis (Hydatid of Morgani); Report of 2 Cases with a Study of the Microscopic Anatomy J Urol Bult., 1945 54 459-

The observation of 2 cases of torsion of the appendix testis by one of the authors in a limited and brief urological experience led the authors of this article to believe that the condition is perhaps more common than reports would indicate. Unless it is realized that the severity of the symptoms produced by torsion of this minute structure may be out of all proportion to the size of the appendix testis the condition may easily be mistaken for other intra scrotal diseases, such as acute epididymitis acute orchitis or torsion of the spermatic cord. In other instances a diagnostic mistake may be made because the initial symptoms sometimes focus attention upon the lower abdomen with little to indicate that the lesion is inside of the scrotum. This occurred in the first case described in this article in which the non scrotal symptoms and signs confused the diagnosis to the extent that the condition was first called acute

Diagnosis of torsion of the appendix testis may be very difficult. In general the symptomatology is that of torsion of the testis. Both conditions occur chiefly in preadolescent or young adult makes in both attacks of incomplete transient torsion with

slight symptoms may have occurred previous to the acute severe episode. It has been said that torsion of the appendix tests does not result in inflammation of the scrotal skin, while torsion of the tests does produce this condition. However in both of the authors cases marked crythems and edema of the skin of the affected side occurred.

Except by palpation of the spermatic cord and the scrotal contents it will be impossible to distinguish between torsion of the testis and torsion of the appendix testis. If there is a tender mass anterior to the testis it may be either the epididymis of a rotated testis or a twisted appendix testis. Differentiation can be made only by careful examination

The epididymis of a rotated tests would extend down the entire length of the testis while an an terior mass due to torsion of the appendix testis would be limited to its upper pole and be movable

upon the testis.

Very little information could be obtained from articles on torsion of the appendix testis regarding the usual histological appearance of this small structure Furthermore textbooks on histology give descriptions that are not entirely in accord For example Bailey's Textbook of Histology states that the appendix testis (hydatid of Morgagni) is a vesicular structure lined by simple columnar epithelium surrounded by vascular con nective tissue. Maximow and Bloom say that the appendix testis is a small nodule consisting of vascular connective tissue and lined with columnar. sometimes ciliated epithelium. Lowsley and Kirwin state that the hydatid of Morgagni is a pedunculated pear-shaped sac from one-eighth to one-third inch long its free extremity dilated and containing a colorless fluid The lack of informa tion on the histological structure in case reports of torsion of the appendix testis and conflicting reports on the histological picture as described in text books prompted the study of 28 appendices testes from the standpoint of their gross and microscopic anatomy

Grossly the appendix testis is a small ovoid or flattened tab of pale gelatinous tissue varying from r mm. to r o cm. in diameter. It is attached to the tunks albugines by a short pedicle. In at least half of the specimens examined, the pedicle was sufficiently long and narrow so that it could have under gone torsion.

Microscopically the appendix testis was made up of loosely arranged connective tissue which was moderately rich in blood vessels. In the connective tissue of some specimens were seen spaces of varying size apparently lined with endothelium and frequently containing a precipitated albuminous material. These structures had more the appearance of lymph channels than that of remnants of epithelial lined tubules. Most of the specimens had a few scattered leucocytes in the tissues. All of the appendices testes were covered by tall columns epithelium which was sometimes ciliated and associated with the columnar epithelium were a few

round pale mucous secreting cells. This epithelium became continuous with the very flat columnar epithelium of the tunica albugines.

Epithelial inclusions were present in 2 of the 35 specimens. The spithelial covering of the appendix testis and the lining of the epithelial inclusions closely resembled the lining of the distal end of the fallopian tube of the female. This would be expected because the appendix testis is derived from the cranial end of the mucllerian duct which in the female forms the fambinated end of the fallopian tube.

#### Francia, R. S.: The Status of Hormonal Biomanny in Malignant Discase of the Testicle. *Brit. J. Surg* 1945, 33, 173.

With the exception of the aeminoma, which is considered to be derived from the spermatic tubule cells testicular tumors have come to be denoted by the name teratoma." and other names depending upon the type of tissue which predominates have been spilled to this group, such as choricepi thelioma, embryonal adenocardooma teratoid carcinoma with cancerous elements and "mixed adult types with carcinoma."

In 1950 Zondek discovered that malignant tumors of the testis caused the unite to give a positive Ascheim-Zondek pregnancy test. In the test and mal a ovary three results were obtained (1) rigen ing of the graafian follicle (2) hemorrhage into the cyst and (3) gross enlargement of the uterine homs It is now understood that the homone output tends to vary indirectly with the degree of cellular mater ity of the tumor However one cannot forceful the histological type of tumor from blossasy of the tumor alone. There is a correlation between the homone levels and the clinical course and consistent high levels usually lead to a fatal outcome It must be pointed out that many negative assays have been associated with malignancy.

The test is a valuable indication of the effective ness of treatment. When the hormone output fails to 400 mouse units per litter within two weeks of the completion of treatment, the prognosis is good. A rising or stationary titer after treatment is a bad omen it is due to local recurrence or metastasis.

The test has various limitations such as varia tions of methods of extracting urine the numbers of mice used per level of assay variations in the inter pretation of overy changes, and the original masses of timese present which give rise to increased hor mone output. In the present stage of the test, the assay of the urinary hormones is not a basis for attempting to foretell the histological type of tumor There is some evidence that the seminomas produce only follicle stimulating hormone and that embryonal teratomas produce both follicle and lutein stimulating bermone (cherionic hormone) Simple orchectomy is the operation of choice, followed routinely by irraduation, especially of the aortic glands, whether or not metastases are suspected This routine would cause fibrosis of the lymphdrainage system and prevent the spread of a possible local recurrence subsequent to treatment.

There is need for a standardized technique of extracting bormones taking 44 hour specimen, making routine analys before treatment and senish during and after treatment uning more than I mouse per level of concentration, making histological section of the mouse every after the test, and which glossasy of the tumor with determination of the two hormones separately. While the range ditter is characteristic for the three main groups—the embryonal terations at the seminous, and the mixed adult terations—the precise pathology of a particular tumor cannot be predicted from the preoperative univary seasy, although low levels suggest either seminoma or the mixed adult type. Follow up tests should be performed for at least to years after treatment—first weekly then at less frequent intervals, and then at six month periods.

DAVID ROSENSLOOM, M.D.

## MISCRILANEOUS

# Burhans, R. A.; Treatment of Orchitis of Mumps. J. Ursl., Balt., 1945 54 547

The so-called entity "orthitis of mumps" is a missioner I has been considered an infection or inflammation involving the testes. In a navil hospital it was observed that the patients do not develop prinarily an orthitis of mumps but an acute hydrocele around the testicle which causes a strangiation of the testicle, in contradistinction to a slow forming hydrocele. This acute process causes strangulation acute inflammatory elema, and ultimate fibrosis and atrophy of the testes. These facts have been substantiated at operation

During the scute scrotal involvement of numps there is a high fever and lencocytosis, but after from 12 to 34 hours the damage has been done even though the temperature subsides.

If a small scrotal incition is made during the scrot orbibits an acute hydrocels is encountered in which the fluid in the tunion vaginalis is under extreme pressure and has a viscid yellowish color. After drainage no other treatment is necessary and the fever simulates a crisis of pneumonia. If drainage in delayed, the tension in the hydrocels essens, the testicle becomes blackish and the testicular tissue presents bulbous edema and infammation.

In early cases of orchitis of momps incision of the acute hydrocele with removal of the drain in 48 hours is indicated and in late cases, the trained proprise and albeginia should also be drained Frentothal soddium anesthesia has proved most attriactory but local anesthesia has not, as the in volved area is tender DAVP ROTERINGON MLD.

Cook, E. N., and Kearing, F. R. Jr r Renal Calculi Associated with Hyperparathyroldism. J. Ursl.,

Balt., 945 54 5 5
Since only 4 cases of proved hyperparathyroldism were observed at the Mayo Clinic from 1929 to 1943 and since this incidence was at a variance with the experience of Albright and his associates who accumulated 67 cases in 10 years the authors made a deliberate search for the disease in the material of the Mayo Clinic from January 1943 to July 1944. They discovered 18 cases I nt of these the patients had only the classical disease of the bone which is observed in hyperparathyroidism while in 14, associated renal calculi were demonstrated and evidence of disease of the bone was minimal or absent

During this same period S50 cases of unnary calculus were seen. Although this would indicate an incidence of 2 per cent of hyperparathyroidsm in cases of urinary calculus, the authors believe that this figure is far too low since only a relatively small proportion of these patients were subjected to a sufficiently careful metabolic study to exclude hyper parathyroidsm completely

A hyperfunctioning parathyroid adenoma was demonstrated in all of the 18 cases of hyperpara

thyroidism.

The frequency with which the diagnosis is made correctly will vary directly in proportion to the thoroughness with which a search is made for the disease. The greatest opportunity for establishing such a diagnosis will appear in cases of multiple or recurrent calculi. Approximately 10 per cent of urinary calculi will recur following surgical removal. The authors believe that this percentage can be reduced appreciably if the presence of hyperpara thyroidism is carefully excluded

The diagnostic criteria of hyperparathyroidsm are hypercalcemia, hypophosphatemia, hypercal cinuma and hyperphosphaturia. Frequently repeated examinations are often necessary to establish a diagnosis. Roentgenological findings may be helpful in cases with associated disease of the bone in cases in which there is uncertainty the authors frequently rely upon quantitative determinations of the calcium in the urine while the patient is on a det low in calcium.

When calcull are present the symptoms are identical with those occurring with calcul- due to other causes. In all such cases a detailed unological study is indicated. It is usually advisable to remedy the hyperparathyroidism first, as subsequent calcull may develop rapidly. It may however be necessary to take care of the urological problem first because of its acute character

Many forms of medical therapy have been tried. Diets low in calcium are unlikely to allevize the renal symptoms and subject the skeleton to the hazard of demineralization. Diets high in calcium increase the tendency toward stone formation Acidlying drugs such as ammonium chloride are of little avail because the increased solubility of calcium in an acid utune is counteracted by a resulting increased output of calcium in the urine.

The treatment of byperparathyroidism is surgical, by removal of the offending parathyroid adenoma, or when primary hypertrophy of all parathyroid issue is involved, by subtotal resection of the parathyroid glands. The unnary calculi already present usually remain unchanged, but in a few instances they have eventually dissolved.

FREDERICK LIEBERTHAL, M.D.

Hellendall, H.: Experimental Transmission of Lymphogranuloma Venereum Virus through the Placenta. Am J Surg. 1945, 70, 320.

Since it is known that the virus of lymphogram lona venereum can invade the blood stream, the author attempted to determine if lymphogramuloms venereum can be transmitted through the placents to the fetus. In 1936 a positive free reaction in a 14 day old infant was observed by Dick. The author's studies in 1942 showed that the antigen prepared from the fetal brains of mice gave positive intradermal reactions.

The present work was concerned with three questions (1) Can the previous work with mice be confirmed with Frel tests in human beings? (2) Can the initial elementary bodies of the lymphogranuloma virus be found in smears and tissues of the fetal brain? and (3) Will antigens from the brain of an intracerberially infected mouse give a positive Frel test when injected into the skin of an apparently healthy offspring of an infected mother?

The conclusion was reached that lymphogranu loma virus is transmitted through the placents to the nowborn before delivery. The clinical question as to whether there is any occurrence of congenital lymphogranulomatosis in human beings should be studied with a great amount of statistical material

DAVID ROSENBLOOM, M.D.

# SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

## CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Mayerding, H W 1 Chronic Scierosing Osteitis. West. J Surg. 1945 53: 413.

The patients included in this series of 80 cases of chronic selectaing outcils were of the average age of 15 years, appeared to be in good health, and were not disabled. The preoperative clinical laboratory findings of the blood and urine were of little value in the diagnosis. Trauma may have been an inciting factor of the condition in 31 2 per cent of the cases.

The outstanding symptom was persistent localized part in 19,3 by error of the cases 16 75 per cent this was associated with swelling. The duration of the symptoms averaged 1.4 years. Sixty five per cent of the patients were males. In 0.75 per cent of the cases the lesions were located in the lower extremity, 50 per cent occurred in the middle third of the shaft of a long bone 50 per cent occurred in the that of the tible or fermer. Fathent aged from 10 to 30 years comprised 60 per cent of the total number

The roent genograms revealed dense spindle shaped cortical regions of sciencist that involved the shaft of the long bones. Translucent regions, small and round, or oval, were often visible. These regions cometimes showed staphylococt on bacterological examination of the material removed at operation and have been looked on as foci of infection producing the aderests.

The treatment is surgical excision and the results obtained are good.

ootamed are good.

Compers, E. L., Schnuts, W. J., and Cattell, L. M.: The Use of Penicillia in the Treatment | Acute Hematogenous Ostromyelitis in Children. A. s. Swg 945 ! 954.

This is a report of 12 consecutive cases of acute hematogenous outcompelltis in children ranging from 3 to 12 years of age which were treated with

penicillin.

Ten of the cases had been resistant to sulfons mides and only 4 required surgery. There were no deaths.

The authors state that penicillin appears to be more effective in the treatment of scute hematog enous esteomyelitis than any other therapeutic

agent including the sulfonamides.

Adequate dotes of penkelllin, from 15,000 to 50,000 units administered every 3 bours day and night, may not only cure the initial infection but prevent spread to other bones and in most of the cases they make surgery unnecessary. If the treatment is started late bone damage may call for late surgery

started late bone damage may call for late surgery
Medical care must not be neglected in these cases.
The fluid balance of the body must be maintained
with normal saline solution, glucose blood or plas-

ma. Splints, plaster casts or traction are used when indicated DASIEL H. LEVISTHAL, M.D.

Marôttoli, O R.: Osteoarticular Lesions in Bru cellosis (Lesiones esteoarticulares de la brucelosis) Rev méd. Reverie 1945 35 8 1

Ostenaticular lesions observed in the course of evolution of bracellovia are characterised as h the disease itself by clinical manifestations of various forms. There are many transitional form between monearticular and generalized polyarticular lesions. From the physiopathological werepoint the syndrome may be divided into two classes. (1) altergia manifestations of the early periods of the disease chiefly in the form of hyperergic reactions of measurabymal osteocarticular itsues and (3) processes confined to one articulation or one osteoperiostal segment, which are the sequelae of the accumulation of specific bacilli. Only the last mentioned group represents the authentic lesions of bracellosis.

Two groups of esteoarticular lesions may be dis-

tingulahed osseous and articular

Opscous lesions in brucellosis are relatively rare and occur approximately in 1.8 per cent of all pa tients if the spinal column is excluded. From the anatomoclinical point of view two conditions may be distinguished, esteoperiostitis and esteomyelith The first mentioned condition may assume a simple form of reaction or may develop into a suppurative lesion. A simple reaction is characterized by pains and roentgenological findings, while suppurative conditions have a chronic evolution. Osteomychts may appear in an acute or chronic form. Osseous lesions produced by brucellosis are relatively benign and show a rapid tendency toward regression and reparative processes. Various types of chronic osteomyelitis such as pseudotumoral condensating, or inflammatory have been described. The diagnosis may be difficult if the involvement of the bones appears in very early stages of the disease.

Articular lesions appear in approximately 40 per cent of all cases of brucellosis. They may assume two forms pseudorheumatism and arthropathies. The first mentioned condition appears nearly exclusively in the acute periods of the disease and may be inter preted as an allergic reaction of the articular mesenchyma to the infection and the toxic effects of bru cellosis. The condition may be monoarticular or polyarticular Arthropathies may be classified as synovitis arthritis and osteoarthritis. Brucellosis shows a preference for primary localization in the osseous epiphyses, invading the articulations sec onderly As a rule large articulations are affected. Generally articular lesions of brucellosis are relative ly benign and no important anatomic or fuctional acquelae are recorded. Occasionally an ankylosis may develop Involvement of the spine has been found in as many as from 50 to 75 per cent of all

autorsies of patients suffering from brucellosts. As a rule spondylitis appears in relatively late stages of brucellosis. Various distinct processes develop within the spinal column viz. degenerative de structive and reparative. The process may involve intervertebral discs. Three forms may be disting guinhed (1) generalized or circumserfbed spondyl lits, (2) a condition resembling Pott's disease and (3) a spondylearthritic form. The symptoms are those of an involvement of the spine due to any cause namely pain muscular contractures deform itles, and the formation of abscesses. There are no characteristic roentgenological signs. Frequently osteophytic and exostotic formations are visible. The process is relatively beause.

The treatment should be directed toward the etiology Spondyltis requires immobilization on Bradford's frame or in a plaster-of Paris cast. Al bees operation may be considered if spondylitis is circumscribed and if an intervertebral disc is in volved Social economic and personal problems should be taken into consideration when a pro-

longed immobilization is contemplated

Joseph K. Narat M D

Soule, A. B., Jr Mutational Dysostosis (Cleidocranial Dysostosis) J Bone Surg 1046 18 8t

Mutational dysostoris frequently transmitted by parents to offspring is characterized by multiple variable skeletal anomalies. The most prominent and frequent of these are aplasis of the clavicles irregularities of dentition and structural shoormal ities of the jawn skull vertherae pelvis, femora exapulae metacaraplas metacarable and phalanges.

A careful survey of the English literature establishes that the first authentic case was reported in 1870 and since then the author's collected cases total 323 of which 198 are familial, involving 52 families. About half of the patients are males Geographic distribution represents every continent. In the cases with a hereditary background there has been transmission by male and female to a nearly equal degree. The condition may appear in several successive generations and then be lost and apparently not reappear in subsequent generations.

The etiology is associated with a defect in the parental germ plasm so that the anlage of the affected bones, both membranous and of chondral origin is thought to be faulty. Various other theories and observations are presented, none is conclusive. Meat of the skeletal defects found in mutational dysostosis are present at birth but may not be obvious until the child develops. The possible variants are so great that no one abnormality is characteristically found in all cases.

A comprehensive discussion of the abnormalities possible in this condition is given and illustrated with photographs and roentgenograms. The dental defects with their complications are most trouble some, and treatment in general is directed toward the alleviation of symptoms. Six cases, two pairs of which were related are presented fully and demon

strate the variability of the defects. The multiplicity of defects which may occur in this condition makes it rational that the term—deidocranial dysostosis be replaced by the more accurate and descriptive term—mutational dysostosis.

FRANCES E. BRENNECKE, M.D.

Smith F M : Late Rupture of the Extensor Pollicia Longus Tendon following Colles Fracture J Bone Surg., 1946 18 49

Late rupture of the extensor polilicis longus tendon following Colles fracture is an unusual complication which results in disability that may be relieved only by operation on the tendon. The author has observed and treated 5 cases of this type on the Fracture Service of the Presbyterian Hospital, New York. These cases are described in detail with illustrations.

The complication has been previously described in the literature and the incidence was given as 1 to 270 Colles fractures At the Presbyterian Hospital New York, the incidence was 1 to 368 The majority of the ruptures have occurred in the left wrist and 4 of the 5 cases reported were in the left wrist and 4 of the 5 cases reported were in the left wrist. The complication is more frequent in females (60 per cent) and all 5 of the reported cases were in females The tendon rupture is more common after the age of 30 years and the age incidence in this series was from 21 to 6x years of are

The cause of the rupture has not been definitely established but it probably follows rather late after acute or chronically repeated trauma Factors such as partial laceration of the tendon by a spicule of bone and trauma from forceful reduction of the fracture have been considered. Numerous cases of rupture have been reported when the fracture was minimally displaced or unrecognized and no reduction had been done. In a of the 5 cases reported the nationts sought treatment late that is 10 days and 2 months respectively after their falls. Neither nationt suspected she had a fracture and since in neither case had the fracture been reduced or the wrist splinted it was impossible to consider rough manipulation or faulty splints as a predisposing cause of the tendon rupture. In the a other cases the latent period of tendon rupture was 25 days, 27 days and 6 weeks. From the operative and pathological findings in the 5 cases it is the author's belief that in rupture following Colles fracture the cause is an aseptic necrosus due to interference with the blood supply of the tendon at the distal end of its groove on the radius.

There are no symptoms prior to rupture which would lead the surgeon to suspect a degenerative process in the tendon. A few patients describe a single sharp pain when the tendon ruptures but most of them describe what they call a sensation of something giving way or a snap on the back of the wrist followed by inability on their part to atraighten or to lift the thumb actively. They may also note difficulty in picking up small objects such as pins. No subjective sensory changes are noted

Physical examination reveals first, a thomb that droops in its entirety, and second, partial feeding of the distal phalans. There is inability to elevate the thumb actively to the same level as the other meta carpals, and it is impossible for the patient to extend the distal phalans actively against resistance all though this can be done passively. The ultims border of the anatomical smulbox is characteristically absent. Occasionally the swollen degenerated end of the distal portion of the ruptured tendon can be felt beneath the skin and subcuttaneous tisne as a small bump. There is no loss of skin sensation over the superficial distribution of the radial nerve.

The site of rupture in the extensor pollucis longus tendon is usually at the level of Lister's tubercle on the donum of the lower extremity of the radius. The datal portion of the ruptured tendon is usually drawn downward and the proximal portion usually retracts upward to the upper edge of the donal radiocarpal ligament or even more proximal to this. As much as 5 cm sometimes separates the two tendons and the radius through which the tendon passes becomes obliterated. A specimen stalled with Schariatch R showed the presence of lat between

the tendon fibers

In considering the operative repair of this condition, the author emphasizes that the extensor pollicis longus tendon has a dual function. Extension of the distal phalanx upon the proximal phalanx at the interphalangeal joint is probably the less important half of this tendon's function. Drooping of the thumb as a whole which is observed in this complication, is due entirely to the loss of the oblique pull of the tendon. Any operative procedure designed to restore full function must therefore restore the oblique pull. Following experiences of the first 3 cases the author recommends auture of the distal end of the extensor pollicis longus to the extensor carpi radialis longus by end-to-side suture following this, the tendon of the extensor pollicis brevis is also drawn over and sutured by a side-to-side suture. The first hookup gives the lift to the thumb and the ex-tensor pollicis brevis adds extension to the distal phalanz. The ideal method of repair by resuturing the tendon ends or by implantation of a free tendon graft is prevented by the adhesions that are present even if they were broken it would result only in bleeding that would produce more and denser ad hesions. During postoperative immobilization the tendon would "freeze" and become nonfunctioning. Upon exploration and repair of the tendon the super ficial branch of the radial nerve should be isolated and protected because damage to it may lead to distressing numbress of the dorsum of the thumb

Following operative cleaver the hand, the wrist and forearm should be immobilized in a volar modeled plaster rollar in slight cock-up position with the thumb fully extended and elevated. The splint may be removed at the end of 10 days and the patient encouraged to begin moving the thumb very gutly in figure and extension. He should then be advised to remove the splint 3 or 4 times daily for exercises and for hot socks. Usually at the end of 3 or 4 weeks it is possible to discard the splint completely at which time the exercises are increased and the patient is encouraged to begin mild active use of the thumb

In all of the 5 reported cases the patients aboved improvement in function and use. The best follow up results from a functional standpoint were found in the cases treated by the operation proposed by the author. Warners, M.D.

Guri, J. P.: Progenic Ostsomyelitis of the Spins. Differential Diagnosts through Clinical and Roentgenographic Observations. J. Bens Sur. 1946, 33. 89.

This article is based on 48 cases of pyogenic orteomyelitis of the spine. In order to arrive at the cor rect diagnosis it was necessary to be very careful in the differential diagnoses. Some of the conditions considered in these diagnoses were scute appendicites, the meningeal syndrome, and the back pain syndrome. The latter was divided into an acute form (16 cases) the subscute form (7 cases) and the insidious form (19 cases) Here the diagnosis rested between the differentiation of pyogenic infection from tuberculosis. The site of the pyogenic infec tions varied they involved the spinous articular process the transverse process, or the laminae. When pyogenic osteomyelitis involves the vertebral body it may be divided into the localized or diffuse form When the diagnosis is tuberculous, in adults, areas of increased density are not frequently found in the roentgenograms of living subjects except when there have been secondary infections hage sequestra, or sudden collapse. There is a definite increase of density and scierous in pyogenic spondylitis thus these features are diagnostic and permit the differentiation between tuberculosis and progenic spondylltis. REMARD J BESSETT Ja., M.D.

Hatcher C. H.: The Pathogenesis of Localized Fibrous Larices in the Metaphyses of Long Bones. Ann. Surg 1945, 12 1016.

Because of the various secondary characteristics which are prominent in the course of localized benign fibrous lesions of bone, a variety of lesions have been described under various diagnoses. Philip and But man and Sinberg described the lexions as solitary xanthomas, while Geschickter and Copeland called them variants of solitary bone cysts or benish glant cell tumors. Phemister described some localized non suppurative lesions of bone as fibrous osteomyelltis. Some of these would now be included in the lesions described as esteoid esteoms. In 1012 Jaffe and Lichtenstein demonstrated the various stages in the development of solitary fibrous lesions of bone and interpreted them as benign tumors formed from mature marrow connective tissue. These were called nonceteogenic fibromes of bone

The anthor reports on 51 lesions found in 45 pt tients and demonstrates the clinical, roentgenolog

ical, and pathological findings in the various stages of the development and regression of the lesion. There were 38 males and 17 females. Five patients had multiple lesions. The lesions had their inception during the period of longitudinal growth. All of the lesions were in the long bones of the lower extremities. Jaffe and Lichtenstein found 1 lesion in the distalend of the ulna. All of the lesions were situated in the metaphysis or adjacent shaft usually eccentric and abuttung on the cortex.

The symptoms are usually mild and consist of intermittent moderate pain often referred to the

adjacent joint, and local tenderness

Reentgenographically there is a limited area of reduced density in the metaphysis close to the epiphyseal disc which in later cases clongates and has a scierotic margin, usually scalloped which gives the abonerance of loculation Later cases may

show periosteal reaction

The pathological appearance varies somewhat with the age and activity of the lesion. Fibrous con nective tissue is the basis of the lesion in all stages The recently formed focus shows a relatively cellular fibrous tissue with scattered multinucleated cells. The older lesions show fibrous tissue arranged in strands and whorls. Lymphoblasts are found scat tered through the fibrous tusue. Lipoid filled macrophages are often present grouped or scattered The lipoid deposition is evidence of chronicity Concomitant epiphyseal disorders were observed in 14 cases Spontaneous healing of the abrous metaphyseal lesions was usual. In only a few cases was surgical eradication necessary for the relief of pain The etiology of metaphyseal fibrous defects is obscure DANGEL H. LEVETHAL, M D.

# SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Robertson, I. M. and Barron J. N.: A Method of Treatment of Chronic Infective Ostellia. J. Bons Surg., 1946, 28-19

The authors treatment of chronic infective extel its in based on the principle of extensive excision of all diseased tissues including skin, deep scars and infected bome and the replacement of soft tissue defects by mucle and skin flars and of bone defects

by bone transplants.

This procedure may require two or three operative stages. In the first stage all of the diseased tissue is excised and a split skin graft is applied to the wound surface. In the second stage there is a plastic repair of the soft tissues. The original split skin graft is removed and the area is covered by a skin and subcutaneous flap muscle being included where necessary. Stage three consists of repair of the bone graft. In some cases the second and third stages may be combined. An interval of 4 weeks is suggested be tween the first and second stages and one of at least weeks between the second and third stages. In some cases the full diameter of the shaft of the bone may be involved.

Several diagrams photographs, and roentgenographs are included in the original article. The details of the operative care in the three stages are discussed at length. A word of warning is given that this is not an undertaking to be lightly embarked upon by the operator.

RICHARD J BENNETT JR., M.D.

Starr D E.: Congenital Absence of the Radius. J Bens Surg 1043 27 572

Three cases (involving four limbs) of congenital absence of the radius in its various aspects have been seen by the author

The most interesting was a bilateral case with congenital absence of the radius the thumb and the first metacarpal bones. The a other patients showed partial or complete absence of the radius and absence of some of the carpal bones. This deformity is disabling and very unsufuly

A three stage procedure is carried out whereby skeletal traction is applied uliar osteolomy is per formed and a fibular transplantation is carried out. The end result is particularly good in that it allows forearm rotation and wrist motion when part of the radius is present, and presents an extremely improved appearance.

RICHARD J BENNETT JR., M.D.

Aithen D M: Late Results of Albee Fixation of Tuberculosis of the Spine. Proc R. Soc M., Lond 1945 38 685

The author states that during the past 40 years the treatment of tuberculosis of the spine has passed through two phases and entered the third. The first phase consisted of fixation of the affected joints on a controlling splint until all pain and swelling had disappeared and the patient's condition was thriving. The second phase may be saud to have begun about 1911 and was first applied in Robert Jones practice, mainly for tuberculous disease of the spine. It consisted in the addition of a bone graft with the object of securing extra-articular fixation and bridging the diseased area to secure more comlete fixation.

The third or present phase is based on the extra ordinary results which followed successful employment of the Robertson Lavalle technique which is briefly outlined. This procedure consists of drilling ruberculous foci which are believed to contain some defensive substance which cannot escape into the general circulation on account of the constriction of the issuing capillaries by the tough capsule about the focus. Drilling into the focus supposed to let this mysterious substance out into the systemic circulation. Only young foci are drilled. These show on the x ray as faint blurred areas of decreased density.

Use of the procedure is said to be followed by marked improvement in the well-being of the patient. Pain usually disappears quickly and the degree of sepsis is lessened

VERNOR C. TURNER, M D

Dulocation of the knee point is frequently associated with peroneal nerve injury and rupture of the poplical artery. The latter complication occurred in 10 legs which had to be amputated because of subsequent gaugeres.

Thirty two patients were unconscious for periods varying from a momentary lapse to several days. They were thrown in a vertical direction up to 115

feet and horizontally up to 200 feet.

The first aid treatment of solid blast injuries is primarily devoted to saving life i.e. the treatment of shock, splinting of the injured parts and evacuation to safer places for definitive medical care

The final management of these patients follows along well known lines. It is noteworthy that skele tal fixation devices (Roger Andersen Stader) were found to delay unno and cause osteomyelitis around the pin holes. Sailors who were in their bunks at the

time of the explosion suffered the least injuries.
In conclusion 13 case histories are described in detail.

# SURGERY OF THE BLOOD AND LYMPH SYSTEMS

#### HIJOOD VESSELS

Gross, R. E.: Surgical Correction for Conretation of the Aorta. Surgery 1945, 18 671.

Researches on dogs were carried out which indicated that the aorta could be completely transected and a normal vascular pathway reconstructed.

Two case reports are included in which the constricted area of the aorts was reserced. In the first case the patient died of cardiac dilatation said to be due to the fact that the blood was allowed to re-enter the great vascular bed in the lower part of the body too rapidly. In the second case a 12 year old girl was studied and prepared for poperation. The operation was carried out successfully in June 1945. The constricted area was resected and a satisfactory end-to-end anastomoris was completed. The patient made an invertiful recovery.

It was interesting to note that the blood pressure in the lower extremities came up to the normal level over a period of several days, while the hypertension in the upper extremities gradually decreased over number of days. Researd | Basvert Jr. MV B

Paul, M : The Surgical Treatment of Traumatic Ansuryama. Brit. J Surg. 945 33 : 3.

The surgical treatment of large ancuryums is attended with difficulty and danger and the successful management of such cases domands a high degree of technical skill together with a proper appreciation of the problems of this branch of surgery. The author presents detailed reports of 8 cases. These indicate how problems have been met in individual instances that are not so common as to be within the experience of most surgeons.

A brief history of the surgical treatment of aneu-rysms is presented. The risk of gangrene of a limb following an operation in which the blood flow through the main artery has been obstructed by the operative procedure should be minimised as far as possible. If the arteries distal to the aneurysm exhibit a normal pulsation it is clear that most of the blood is still traveling through the main artery. In the traumatic cases the ancurvam is likely to be saccular and suitable for treatment by the restorative endoaneurysmorrhaphy method of Matas which carries almost no risk of interference with the main circulation through the limb If on the other hand there is no pulse in the arteries distal to the aneuryam, it is clear that the circulation is being carried on mainly by collateral vessels and Matas advocates that the deficiency of the collateral circulation be estimated by the following method

The lumb is blanched by elevating it and by the application of a firm elastic bandage. The main artery is now compressed above the ancuryan the elastic bandage is removed and the limb lowered. If the collateral circulation is efficient, there should

be a blush in the blanched limb within 3 minutes. If the collateral circulation is deficient, it can be improved by removing the sympathetic vasomotor control to the limb either by the operation of sympathectomy or more temporarily by the injection of the sympathetic field with novocasis.

In conclusion the author notes that among the 8 cases of aneuryams described, the aneuryam variation to the aneuryam variation to the aneuryam exhibited almost normal pulsation. In these cases the Matsa operation for reconstructive endoaneuryamorrhaphy proved thoroughly practicable, the patient being cure dy the operation.

In a cases the ancupyon was traumatic and fund from. The strete distal to the ancupyon showed nor pulsation. Maias obliterative codosneury-morthaphy served, however to cure these patients of their ancupyons. In I case which unfortunately proved fatal, the ancupyon was due to the rupture of an arterioscierotic calcified vessel. In this case the ancupyon had caused gangeren of the foot, which necessitated a disarticulation through the hip joint.

Hauser F Townson, M.D.

Buxton, R. W. and Coller F. A.; Surgical Treat ment of Long Standing Deep Philebitis of the Leg. A Supplementary Report. Surgery 1945, 18 661.

In the group of cases studied the long standing deep philobilits of one or both lower extremities had its onset from a months to 30 years previously. Ligation of the femoral wein was carried out in individuals who had pain or disability resulting from chronic deep thrombophichilis. The authors say get that hystin of the femoral wein abouth not be carried out beyond the age of 55 years because of the advanced atterfal diseases. Superficial varies were treated by ligation before the iemoral wein hysticas was carried out. The injection method of treatment of varieous evens was not used before, during, or after femoral ligation and none of the patients had received lumber sympathetic block before during or after femoral year ligation.

Of the 14 patients with alceration, 6 have had complete bealing of the ulcers for z year or longer Others were healed for a shorter period of time. In a patients the areas are still unbauled. Reports in dicate that there has been little improvement in the degree of swelling as compared with the prooperative status. Fatigue without exception continues to be a permanent symptom. When involvement way sent at hove the level of the profunds femority, rein ligation of the common femoral vein was carried out it is believed that the level of vein ligation above or below the profunds femoris, profunds femoris profunds femoris patients when the profunds femoris in the vein the profunds femoris branch bears little reis ton to the degree or duration of postoperative edema, to the appearance of superrical variest postoperatively or to the end result.

The common iliac vein was ligated in r patient. Postoperative lumbar procaine injection produced

little change in the patient s leg

The inferior vena cava was ligated in 7 patients with a longstanding philebits of both lower extremities. The first patient upon whom a ligation of the vena cava was performed has now passed the twelve month period following it, and has no edema, although a prolonged trial without external supports as not been made. All the other patients in this group are still wearing supports. The outstanding end result in ligation of this type is the high includence of healing of ulcers due to stasis. The most disappointing results have occurred in patients upon whom ligation was carried out when such ulceration was not present. The treatment has not been very satisfactory in this group.

RICHARD I BENNETT JR. M.D.

# BLOOD; TRANSFUSION

Corelli, F: The Rh Factor the Cause of Fetal Erythroblastosis Hemolytic Disease of the Newborn and of Transfusion Reactions (II fat tore Rh causa dell critroblastosi fetale, malattia emolitica del neonato e di reazioni da trasfusione) Palidinico (res. prat) 1945 52 359

This article is almost entirely a review of the American and English literature on the Rh factor which has already been ably reviewed Its purpose is to acquaint such part of the Italian med cal profession as is not already well acquainted with the subject—with the possibilities in the duagnosis and treatment of anemias edemas purpuras, and ictene conditions of pregnancy and infracy and with the explanation of many instances of abortion or premature delivery Of course, many Italian doctors have been working in this field, for instance, Pontano has been transfusing with blood which is negative to the N factor.

The author himself finds an explanation of some of the mishaps in the past. For instance r of his recently observed patients who 3 years previously had received a number of transfusions without incident received another harmless transfusion incident to the development of a marked hypoplastic anemia. Thirteen days later she received another homogroup transfusion, which was suc ceeded an hour later by a typical severe reaction. Of course the mishap might be ascribed to the inadequacy of the crossmatching tests and even of the so-called biological test (an initial injection of 20 c.c. of the donors blood with observation for 5 minutes thereafter) However, the author thinks that the patient had received blood in one of the previous transfusions which was positive for the Rh factor then in the first of the current two transfusions the blood was Rh negative and in the second it was Rh positive and this brought on the reaction. However the patient fortunately recovered.

Considerable space is given to the correspondence section of the Journal of the American Medical As

sociation (1945 127 1146) in which Darrow claims that Rh positive blood should not be harmful to the erythroblastic infant. She postulates the correct methods of treatment for the condition, reserving perhaps for further study the question of transitusion with Rh positive blood and her opinions are accepted without reserve. The author also with apparent benefit has alkallinized the urine with bloarbonate of soda (a gm. every 4 hours) and ad ministered sodium lactate (Fox JAm.M.Ass 1944 124 127) for burn patients.

The author is now trying to build up a roster of Rh negative donors at the Uniti Hospital in Rome and intends to study further not only the question of the Rh factor but also the possibility of explain ing the surprise reactions among the homogroups themselves in which the Rh factor does not always seem to be culpable. These reactions occur even in the O group and are possibly due to other as yet little noticed factors such as the factors M N and He believes that other matters also should be included in these investigations such as the influence of the Rh factor in the unexplained occur rence of mental debility in children, as a high percent age of Rh positive infants delivered from Rh negative mothers has been found to be mentally deficient.

All of the aspects of this problem have been in cluded under a broader conception which the author has designated as "Hemopathic Allergy His book on this subject was published in 1944 by the publish ing house of Pozzi in Rome.

JOHN W BRESHAM M.D.

## LYMPH GLANDS AND LYMPHATIC VESSELS

Moreton, R. D: Lymphosarcoma with Primary Manifestations in the Gastrointestinal Tract. Report of 7 Cases Studied Roentgenologically Tests State J H 1946 41 458.

Lymphosarcoma is defined by Ewing as a true malignant neoplasm arising in lymphatic tissue from prohieration of atypical lymphoid cells This occurs as (1) a localized or (2) a diffuse process. It is one of the larger groups of tumors referred to as malignant lymphoma or lymphoblastoms and should be classified under this general heading

Because of the relative ranty of this condition the author thought it was advantageous to present a brief review of the pathological and roentgenographic findings as well as to present; cases of jumphosarcoma which manifested themselves as gastrointestinal lesions and were studied roentgenographically.

Two types of this tumor are recognized the small cell lymphosarcoma or malignant lymphocytoma, and the large cell or reticulum cell lymphosarcoma. Some authorities believe the distinction between the two types is important from both therapeutic and prognestic standpoints. In the gastrointestinal tract the growth originates in the submucosa and invades in each direction involving on one hand the

mucosa, and on the other the muscularis of the bowel.

In summarizing the author notes that the term tumelactive lesion" should be a useful one in the reentgeological field just as in gross pathological diagnosis. This term is used as a general one and does not define a specific etiologic or histological process, and is therefore used before the more refined.

methods of diagnosis are employed

Madiologists among them at to believe that receiptopologists is aming them as he made to estabbish the presence of any tumefactive lesion in the gastrointestinal treat at least as early in the ama tomic development of the lesion as the latter is also to cause symptoms and be mailfested by clinical signs. A necolpatic lesion may be distinguished from a non-neoplastic lesion may be distinguished from a non-neoplastic lesion with about the same accuracy after the examination of the gross specimen. Surgical exploration has abstantiated these beliefs to the extent that such reentgenological caps billities are well recomined.

Due to the rarity of lymphosarcoms as compared to carcinoms as well as the similarity of lymphosarcoms in the gastrointestinal tract to that of carcinoma in the same location, there is the tendency to report all of these lesions as carcinomas rather than tumefactive lesions or malirant neonlasses at the

particular site noted.

In this condition the roentgenological findings are not sufficiently characteristic to allow a specific diagnosis of lymphosarcoma of the gastrointerinal tract and for the reasons which have been stated carcinoma is the diagnosis that is most frequently made.

In conclusion, the author states that 1 new case of lymphos aroons with prinary manifestates in the gatrontestinal tract have been presented. The series included 5 women and 2 men. The locuspers patient was 21 years of age the oldest, 74. No distinguishing features of lymphosarroms were found either in the history or on roentgenological grantation. The y leakons viewed roentgenologically had an appearance indistinguishable from that of exchanges.

All patients were subjected to an exploration, operation, the diagnosis being made from blopsies. Fire of them were subjected to postoperative roengen therapy as noted in the case reports. Fire of the 7 patients have died one, 10 days postoperatively of bronchopocumonia and the others, 75 months 2 months, 10 months, and 2 months, 15 months

Two patients with involvement of the atomach were last seen at the clinic 34 and 36 months after their first admission. They showed no evidence of recurrence One of these patients had been treated by resection and postoperative irradiation the other.

received irradiation alone.

# ANTISEPTIC BURGERY; TREATMENT OF WOUNDS AND INFECTIORS

Weinstein L. and Wesselhoeft, C.; Penicillin in the Treatment of Tetanus. \ England J M

Two cases of severe tetanus are reported in which recovery followed treatment with large amounts of antitoxio, surgical excision of the wounds and admin istration of large doses of penicillin

Bacteriologic studies revealed that clostridium tetani could no longer be isolated from the wounds in these patients a4 hours after the first administra tion of penicillin. The aiready demonstrated antibiotic influence of penicillin on this organism in vitro therefore, appears to be confirmed in vivo

The use of penicillin in tetanus appears to be most valuable in cases in a hich multiple lesions not all of which can be removed by surgical means, are present or in which no focus of infection is detectable. This antibiotic agent is not intended to replace the admin latration of antitoxin, excusion of wounds, adequate sectation, and maintenance of a normal state of nutrition and hydration, but appears to be a highly important adjuvant to these other therapeutic

McAdam, I W J : Penkellin Treatment of Acute Hematogenous Osteomyelitis. Brit. J. Surg

The liferaving properties of penicillin are discussed, and its limitations in local infection and bone necrosis are emphasized in conjunction with 40 patients in whom penicillin treatment was used The long bones were affected in 32 of the patients. Ane roug outer were entered in 35 of the persons. The must daily dose of penicillin was 100 000 units larger doses were used when indicated. Quite a wide variation in the serum level of penicillin was found

Intramedulary injections of the penicillin produced a higher concentration in the pus. The intra-medullary method is recommended when the in fected metaphysis is intracapsular and there is an almost inevitable septic arthritis. It would appear from the results reported here that a route for the rom an results reported from the metaphysical focus to the infected joint cavity is open. The introduction of a needle into the medulis of an infected bone serves several purposes it allows the aspiration of a subperiosteal abocess it relieves intramedullary tension and it allows a bacteriological diagnosis to be made from the pus in addition, it is used to ad

The length of time that organisms are found in the medullary cavity is very important in order to deckie the duration of treatment. Among 18 pa tients, the average time for staphy lococcal infections to be cleared up was 14 days, and the treatment was continued until three successive daily specimens of

pus proved to be sterile. The temperature chart and leucocyte count were not found to be reliable as guides to the severity of the local infection. Of to patients 31 had a generalized infection, 10 had metastatic foci, and 30 had positive blood culture.

A large table is given in the original article, show ing the details of treatment in 40 cases of acute hematogenom osteomyellitis. Among 32 patients with acute infections of the long bones treated with penicillin, 5 had operative treatment and the remaining 37 were treated conservatively. In 10 of the 40 ing ay were treated conservatives) in to or the 40 patients septic arthritis occurred. This complica tion is most effectively treated by the appration of pen and the local injection of penicilin into the joint cavity every second day Among 22 of the 32 jour carry erery section day Among 22 or the 32 patients who had infections of the long bones, 2 have poor function because of destruction of a joint 1 patient developed a pathological fracture and patients have discharging sinuses. In the remaining 17 patients, good function has resulted.

I enicillin treatment sterilizes bone in an average of 14 days. Before sterilization, however bone damage has occurred, even though it is not evident roentgenographically Immobilization would appear to be advisable until there is roentgenographic evidence of recalcification.

In this series of 40 patients 19 had a staphylococ cal septicemia o had metastatic lesions, and 10 had a septic arthritis there was I death.

RICHARD J BERRETT JR., M.D.

Kirby W. M. M., Leifer W., Martin, S. P., Rammelkamp, C. H., and Kinzman J. M.: Peni cillin in Oil. J. Aw. M. Att. 1945, 189, 940.

Penkcillin becswax-peanut oil mixtures provide an effective and safe means of prolonging the action of penselllin in the body Studies were made of the absorption and excretion of penicillin following intramuscular and subcutaneous injections of 300,000 units of penkellin in a 4.8 per cent becawas in oil mixture. A single injection was administered to 54 patients with acute gonococcal urethritis and 35 patients with primary or secondary syphilis re ceived 8 daily injections, a total of 2,100,000 units in

Calcium penicillin was used rather than the sodium sait because it was less hygroscopic, although there was thought to be no significant difference in the duration of the blood levels or in the clinical results because of the particular salt used. Penicillin was suspended in a 4.5 per cent becawar in oil preparation. Intramuscular injections were made into the gluteal or deltoid muscles, and subcutaneous injections into the subcutaneous thanes overlying the insertion of the deltoid muscle. The variability of absorption and excretion was striking the important factor being the location of the injected material in relation to the muscle tissue and inscial planes, while the activity of the patient was apperently of minor consequence. It was concluded that there must be a continuous absorption from the muscle of a large amount of penicillin to insure absorotion of about 2 500 units per hour Slower more uniform absorption was obtained with subcutaneous miections because there are fewer and smaller blood vessels in the subcutaneous regions than in the deep muscle tissues therefore this route was considered superior although it was used in only 25 cases in

Penicillin levels in the blood and in the urne were obtained in the 89 cases The blood levels were determined by the Kirby Rantz modification of the Rammelkamp serial dilution technique (which detected as little as o o4 units per cubic centimeter) and specimens were taken 14, 1 4 8 12 16 20 24, and 28 hours after the injection. In 69 per cent of the 54 patients with gonococcal urethritis the blood levels were present for no longer than 12 hours and m about half of the 31 per cent in whom the levels were present for from 16 to 28 hours irregularity of absorption during the second 12 hours was noted In only 7 per cent of the 35 luctic patients assayable levels of penicillin were present 24 hours after each mjection. No cumulative effect of penicillin was noted In both groups of patients urine was col lected in 12 hour periods for from 48 to 72 hours and follow-up clinical observations were performed for a minimum of 21 days The excretion of penicillin was found to decline rapidly after the first 12 hours but small amounts could be detected for 72 hours or more. The urinary excretion confirmed the evidence of superiority of the subcutaneous over the intra muscular route of injection

In the one third of the patients who received subcutaneous injections it was observed that the absorption was more uniform and the levels were more prolonged in approximately two-thirds of these patients penicillin was present in the blood in de tectable quantities for 24 hours or more

From the preliminary clinical results it is concluded that, although larger amounts of penicillin are required than with penicillin in saline solution, penicillin-beeswax-peanut oil mixtures provide an effective and apparently safe method of prolonging the action of penicillin in the body It is further con cluded that an injection of the penicillin in oil mix ture (300,000 units) should be made twice a day for treatment of infections in which it is desirable to maintain a therapeutic concentration of penicillin throughout the duration of treatment.

Soreness at the site of injection which persisted for 9 or 10 days was the only significant manifesta tion of the penicillin in oil injections (3 of the luctic cases developed a generalized urticaria) and this was less severe in the subcutaneous administration

PRILIP B CHASE, M.D.

# ANESTHESIA

Pleasance, R. E. Intravenous Anesthesis in the Tropics. Current Res Anerik. 1945 84 231.

This article is based upon experiences at a Base Hospital, and covers a period of 23/2 years with intravenous anesthesia mainly pentothal sodium.

During this period 3 994 of 7 952 anesthesias, approximately 50 per cent, were intravenous anesthesias of some form There were no fatalities in this series and no definite postoperative pulmonary com plications. The operative cases varied considerably and included most types of minor surgery and diag nostic procedures, as well as maxillofacial, plastic orthopedic, and extensive surgery of the cranial vault, chest, and abdomen Pentothal alone was used when possible but the more extensive procedures were performed under a combination of pentothal and some other form of anesthesia, prefer ably gas and oxygen

The author lists the following types of cases as

suitable for intravenous anesthesia

Patients who desire to avoid unpleasant inhalation agents.

Patients who resist other forms of anesthesia Patients who are unable to tolerate a mask over

Patients who have had little or no premedication.

Patients who require a supplement to spinal anesthesia. Patients who are subjected to minor operations

manipulations or examinations under anesthesia. Patients who are subjected to selected major

operations Patients who require an antidote to the toxic

effect of local anesthetics. Patients who are having convulsions from drug

poisoning ether or tetanus.

Patients who require sigmoidoscopic or cystoscopic examinations or application of the diathermic

The tendency toward laryngeal spasm makes the use of pentothal for bronchoscopy hazardous unless an expert in the arts of both anesthesia and bronchoscopy administers the pentothal Lundy's method of reinforcing the preliminary infection after a few minutes of waiting and proceeding to a deep plane is advocated.

The following patients are not suitable for intra

venous anesthesia

Children under 7 years of age Patients with severe liver and kidney disease

Patients with suppuration in the neighborhood of the neck

Patients with cystitis and latent pyelitis

Possibly patients with asthma and those who have been treated with preparations of sulfanilamide, those with dyspnes from any cause, with severe anemia, cachexia and dehydration with cardiac decompen sation, with hypotension, or with varicosities are also unsuitable for intravenous anesthesia

In this extensive series, the author noted some complications such as venous thromboses, severe headache, unusual urticarial-like erruptions, vomit ing, exacerbation of latent malaria, priapism factitation, and intra-arterial infections eventuating in the loss of the extremity

Since barbiturates are broken down in the liver and excreted by the kidneys great care must be exercised in the use of pentothal in a tropical climate, where liver disease or deficiency is comparatively common. The fall in blood pressure and depression in respiration depend upon the rapidity with which the aneathetic agent is injected. The four stages of aneathesis discussed are light narcosis, the "stage of incipration aneathesis, and premortem."

Induction, as well as recovery is quiet, but occasionally the patient is irrational, noisy and hyper active. Whenever possible, the solution (2 5%) abould be freshly prepared at least 10 or 12 minutes before injection. Preoperatively the patient should be prepared as for a general anesthetic, and if the procedure requires a prolonged anesthesia, morphine (gr 36) and atropine (gr 1/100-1/150) should be given. The following techniques of administration are used (a) the single dose (b) the intermittent dose and (c) the continuous dose. These techniques were dependent on whether the case was (1) a simple surgical procedure, (2) a general surgical procedure requiring prolonged anesthesia, (3) a cerebral case, (a) a case of maxillofacial surgery or (5) a case of thoracic surgery Postoperatively routine use is made of one of the detoxicant drugs-coramine, phrenazol, or picrotoxin, and the patient is carefully watched until the return of reflexes or even consciousness. The author judiciously concludes. The ease of its administration may constitute the greatest denger of pentothal." DAVID H. LYRN M.D.

Edwards, G: Tribromethyl Alcohol (Avertin, Bromethol) Proc. E. Sec. 11 Lond, 945 39 71

The author describes the first case narcotized by avertin in England as well as additional experiments with the drug up to the present time. It is now being administered routinely

This drug has had widespread popularity from its initial introduction into England in 1927. In 1936 so per cent of the hospital patients and 69 per cent of the patients in nursing homes were given avertin. However its popularity has wanted since that time during the last 1 as months less than 5 per cent of the

horpital cases and less than 10 per cent of the private patients have received this drug. A 1/10 ga, per klogram dose has been used from the start. The original 3 per cent solution used has been changed in a 2/5 per cent solution used has been changed in a 2/5 per cent solution. The Compo red test was used to determine traces of hydrobromic sch. Rectal plags and postoperative washout were used at first but were soon discarded as worthless. It was soon learned that averties should be given as a basis aneathetic only total aneathesis with the drug was found to be dangerous.

Avertinized nationts retain an active couch reflex. Coramine gives an effective counteraction to an overdose. Although avertin is unlikely to damage a healthy liver it should be avoided if there is any suspicion of impaired hepatic function. It has little effect on renal function and nitrogen excretion. It is not recommended for chest surgery because prolonged basal narcosts is found to be a contributing factor in postoperative chest complications. There is no contraindication to its use for throat surgery It is indicated in hyperthyroid patients and those patients who prefer to be asleep before going to surgery It is contraindicated in inflammations or lesions of the rectum or large bowel, in operations in the region of the rectum, and in any condition which produces a definite deviation from the physical normal, such as fever anemis, obesity cardisc or respiratory affections and renal or hepatic lesions.

The author's present routine consists of administring an enemal from 6 to 1s hours before surgry and giving atropine (gr. 1/100) to minutes following the avertin injection. The avertin dose is 1/10 for a gram per kilogram with a maximum of 8 gm. Trichhorethyl sloohol was used in a group of 18 cases. This drug was found to be more hypomotic and to cause less respiratory depression than avertin. It caused excitement both during the onset of nat costs and during recovery and the eighteenth case presented cardiac failure early during the orset of narrous. For this reason the use of trichhorethy alcohol was discontinued. Mark Kars MD.

# PHYSICOCHEMICAL METHODS IN SURGERY

## ROBNTGENOLOGY

Packard, C. Roentgen Radiations in Biological Research. Radiology 1945 45 522

This article summarizes the study of the effect of the roentgen rays on living cells since Roentgens discovery in 1895 and the use to which these effects have been put in biological research. It was descovered early that x rays were of little use as a bactericidal agent, but that large doses resulted in the congulation of plant and animal cell protoplasm. There was early recognition of the sterilizing effect of the x rays on animals and both radown and roentgen rays have been of use in analyzing the role played by the cytoplasmic portion of the sperm and eag since it has been found that the nuclei of gametes can be injured in varying degrees without pre-

venting cleavage of the egg Three types of chromosome change following irradiation have proved important cytogenetically by causing an increase in the number of mutations and chromosomal aberrations over the rate found in nature, and apparently giving rise to the same al terations in the hereditary material as in the spontaneous cases x rays furnish a valuable means of study of such phenomens. The first of these small changes consists of the increased stickiness of pairs of chromosomes which causes some of them to stick together instead of separating during the maturation process with resultant hereditary changes in the offspring Radiation may increase the frequency of this phenomenon over that found in the offspring of nonirradiated parents by as much as 20 times. The second of these changes consists in the sticking together of certain portions of the chromosomes and their subsequent breaking apart under the pull of spindle fibers with subsequent reattachment of fragments either to the same chromosome in their original orientation or in reverse position or to the broken ends of other chromosomes. Precise deter mination of the chromosomes involved and the fate of their parts has been achieved in careful experi-ments. The third effect is a change in the gene itself which greatly increases the mutation rate (Muller in 1927 working with drosophila) this increase is proportional to the amount of energy

absorbed.

Sensitivity to radiation changes rapidly during mitosis, but whether prophase metaphase or telephase is the most vulnerable period is still in dispute. It was demonstrated by Bergonie and Tribondeau in 1906 that the sensitivity of cells in general varies with their reproductive capacity and inversely with their degree of differentiation, and it has been established that during the development of an organ in there is a progressive loss of sensitivity. All though decrease in sensitivity is synchronous with decrease in growth velocity experiments which

induce increase in the normal growth rate have not produced a comparable increase in radiation effect. It appears that when cell division and metabolism are at a minimum as during chilling cells have a better opportunity to recover from their injury but Henshaw and Francis working with wheat seeds found no quantitative relation between susceptibility and water absorption oxygen consumption and mitosis although sensitivity rises when water is absorbed and growth commences.

There is general agreement that the primary effect of irradiation on the tissues is an ionisation, resulting in transformation of complex molecules to simpler ones but the precise point of primary attack and the pattern of chain reactions which may be precipitated has yet to be worked out. A rays have been repeatedly shown to have no direct effect on oxygen consumption but work by Crabtree and Gray indicates that they have an effect on glycolysis and work by Dale that they inactivate dilute carboxypeptidase while Sparrow states that perhaps the sensitivity to x rays may be correlated with the nucleic acid metabolism.

In 1904 Keemicke demonstrated the ability of organisms to recover from x ray injury but it was not until 1932 that Henshaw offered quantitative data in proof of the generally accepted principle that when x ray intensity is low the rate of repair is sufficient to balance the rate of injury. He found that when arabacia eggs are irradiated and then fertilized, he onset of division is delayed the delay being an exponential function of the time interval between the end of exposure and the moment of fertilization and the period of recovery apparently being limited to the quiescent interval between ir radiation and fertilization.

LILIAN DORALDOOM, M.D.

Sinberg S.E., and Burman, M S: Roentgenologic al Visualization of the Fractured Temporal Styloid Process. Radiology 1945 45 599.

The roentgen visualization of the temporal styloid process is often difficult. The lower part of the bone may be seen in posteroanterior roentgenograms made for the demonstration of the maxillary sinuses, in the open mouth view of the edentialization patient, and in the lateral view of the nasopharynx and neck, but the entire bone is shown rarely

The authors became interested in the roentgen visualization of the styloid process in connection with a rather unusual cases which are described in the text and illustrated with their respective roent genograms.

A technique developed from that of Kaplan was found to be of definite value. It is given as follows For visualization of the right styloid process, the patient is seated in the right oblique position (about x degrees) with head bent to the right at an angle of

about 10 degrees. The head is extended about 10 about to negrees the mandible out of the line of the actives to mine the manning one or the manning and any of the patient s ayyon, the cameric is placed upon the patient at the shoulder and held firmly against the side of the neck and head by his right hand. The veray tube is set from so to 30 cm. to the left of the patient approximately to cm. anterior to and at the level of the patient a kneer. The tube is then tilted appeared about 45 degrees and backward about 30 degrees, so that the central ray enters the left side of the neck in an oblique and upward direction from 3 to 4 cm. below the angle of the mandible

By making use of this technique the authors were able to demonstrate a fracture of the temporal st) loid process in both cases.

Renander A.: Roemtgenologically Examined Case
of Cancer of the Thrums Gland (Roetenoloracial interachier Fall von Cland (Roetenoloracial force).

The concentus of reentgenologists is that roent genegating of malignant tumors of the thymns grand are not characteristic enough to allow a definite diagnosis. However Lenk called attention to cer tain features which permit a correct diagnosis in a tam sectors which permit a correct magnon in a large percentage of cases. The author of this article arge puternage of cancer of the thymus gland in which the picture differed in certain respects from that considered as characteristic for malignant tu

According to the prevailing opinion the medullary substance of the thymns gland is of entedermal origin and therefore belongs to the epithelial structures same the cortical substance is formed mostly by cells deriving from lymphocytes. It follows that malignant meduliary tumors of the thymus gland may be considered executomas while cortical tumors may oe consucron carcinoma, while correct immorphology to the group of lymphoarcomas. This classification must be kept in mind when x ray irradiation is employed for diagnostic purposes because a car a companyed to the thymin stand is very radiorentiant cusoms or the taymus gand is very regionerations while a stream yields to the therapy promptly resembling the lymphotarcoms of the mediational control of the mediations. semants on the respect. In this manner a carcinoma can be differentiated from a lymphosarcome.

The clinical picture is dominated by pressure symptoms. Frequently signs of congestion in the aympuons. Frequency was a conserved and an original and an original step in the superior vena cava are noticed later on dyspines, cacheria and metastases develop

According to Lenk, malignant tumors of the thy mus gland located in the anierior mediastimum form more or less symmetrical tunefactions which as a rate reach the base of the heart. In contraditioning to glandular tumors located in the antenor meditato ganatuse tumors forceton in the america measurements thank the upper border of a thyrous tumor does not reach the juguidum. As a rule styrous tumor does a rounded shape with polycycle, marging, while the control of the control o as a remain maps with payer on making white glandular tumors form relatively short arches. Long arch formations are characteristic for thymns tu more. Contrary to glandular tumors the transverse diameter of thymns tumors exceeds that of the longitudinal diameter this being due to the growth of

thymus tumors within a preformed capsule. In rentgenograms the thymus tumor forms a shap outline unless the tumor mass penetrates the capate and infiltrates the adjacent pulmonary theres. A thymus tumor usually causes a displacement of the taymus tumor tomany causes a correctly follers, and anentysms are characterized by an asymmetric al shape

In a case of malamant thymns tumor in a 75 year in a case or management traymus trums in a 73 year old man observed by the author, the type of the out man observed by the author the type of the mediational fumor could not be determined from memasumar tumor count not or uncommon mem gennageau). A percent of the parent marks and an enlarged cervicel gland suggested malignancy. The diagnosis was supported by the asymmetrical shape and an extension of the mediatinal fumor into the fight cervical region A complete regression of the right convices gland under the influence of 1-ray treatment supported the diagnosis of malignancy of a lymph gland. On the other hand the outlines of a tytulut giant. On the contemporaris were sharp long polyo die arches were noticed, and the transvene power of the shadow was alightly longer than the constitution of the microscopic examination of the microscopic examination of the tumor revealed a cancer of the thymns stand

Dunner L. Hermon, R., and Begnall, D. J. T.,
Pneumoconiosis in Radiator and Boller Fig. Inhers. Bell, J. Radial 1945 181 377

Chest roentgenographs of 13 boiler fettlers and additor finishers aboved signs of poeumoconoist in Chesta and Assablica Sample Late, and the About in Only 2 had duabling complaints and the chest films of 1 of these 2 firm were essentially negative. The authors attribute the reentgenegraphic finding toe autoors attribute the recutemographic minings to inhalation of dust consisting of and (from the casting mods). For, and oil. The exposure maged from 9 to 36 years.

An analysis of 3 dust specimens, which were obtained by different collecting methods, showed that the content or from ranged up to 6 5 per cent depended on the size of the particle. The amount of soluble will be soluble and the size of the particle. of solable silica did not exceed 0.45 per cent. The average size of the particles was 5 micross in the antiltered specimen.

Wilson, A. K.: Roentgen Examination in Con-fectual intention! Obstructive Defects in In-fants. Am J. Roentf. 1945, 54, 495.

The author presents 3 cases of congenital obstructing anomalies of the intestinal tract in newborn infants, and describes the rocatgen techniques used in accretaining the point of obstruction. For cases of imperiorate anna and rectal atresis bo

uses the method described by Wangensteen and Rice these the helical described by wangements are conin 1900 whereby 52s in the large intentine is used to
delibeate the bland end of the rectal pounds by grathese the bland end of the rectal pounds by grapending the infant head down and placing a radio-Paque object In the anal dimple. This demonstrates the extent of separation between the blind end of the rectum and the perineum to aid the surgeon in deter mining whether a perincal approach is feasible. In

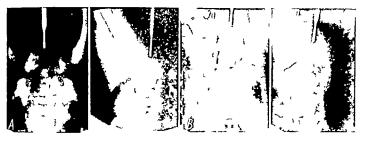

Fig. 1 Case 1 Anteroposterior and lateral views made (a) immediately (b) 5 minutes after and (c) 10 minutes after the infant was suspended head down. Note gradually increasing ascent of gas in rectal pouch, and that there is greater clarity of detail and less risk of erroneous measurement in the lateral projection. The tip of the thermometer is in contact with the anal dunde.

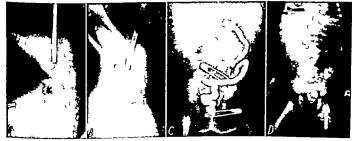

Fig. 8 Case 5. The findings in (a) reproduced from a roentgenogram made to minutes after the infant was subpreded head down, show evidence superstive of high rectal imperioration. This was disproved by insuffaction of air (b)

and the injection of iodized oil (c) The partially calcified enterocyst is seen in (c) and (d) in close proximity to the mobile proximal end of the colon.

cases showing an anal pouch, injection of opaque medium is recommended for an accurate estimate of the depth of tissue between the anal membrane or

perineal surface and the blind end of the rectal pouch. In one of the cases presented a per cent lactose was given by mouth some hours before examination in order to increase cas formation in the bowel in the newborn. Roentgenograms were then made at least and preferably to minutes after the infant was inverted in both the anteroposterior and the lateral projections. It was found that if films were made immediately after inversion the gas might not have reached the distalmost portion of the rectal pouch whereas the gas localization after to minutes corresponded well with subsequent surgical findings. The lateral projection was found of greater value in estimating the thickness of the tissue between the rectal pouch and the perineal skin surface since the pelvic curve of the intestine foreshortens the distance between these points in the anteroposterior view The latter projection may be of value however in demonstrating possible deviation to the left or right of the terminal end of the rectum.

The first case was that of a premature male infant, with no anal onfine but with an anal dimple. It was given 16 ounce of 5 per cent lateries by mouth approximately 12 15 and 18 bours after birth, and at a bours was supposed the down with a thermometer tip in apposition to the anal dimple. Anteroposteries and lateral films were taken immediately and 5 minutes and 10 minutes and

neous margin.

The second case was similar to the first. The third case was that of a premature female infant who developed persistent projectile vomiting about a hours after birth. The first films (Fig. 2) made as hours after birth by the method described tended to support the clinical impression of high rectal atresia as there was considerable distance between the tip of the rectal catheter and the col lection of rectal gas. The insuffiction of air and injection of 15 c.c. of loduzed oil however, demon strated free passage up the colon as far as the transverse portion which was displaced to the left by a large movable partially calcified cystic mass. In spite of fleostomy the infant died to hours after birth. Autopsy showed a large enterocyst joined to the terminal fleum by a fibrous strand and to the mid fleum by an almost atretic loop while the terminal fleum ended blindly a few centimeters from the colon.

Cases 2 and 3 were the only cases of imperforate arus or intestinal atresiz found among 9,474 living babies born in the Hospital of St. Vincent de Paul Norfolk, \a. between 1933 and 1944.

LILLAN DONALDSON M.D.

Issue, Fr Roentgen Findings in Amelic Disease of the Liver Radiology 1945 45 551.

The author calls attention to anothe disease of the liver manifeated first as a diffuse hepathis and progressing in some instances to the formation of solutary or multiple liver abscesses, as the most common complication of amebic dynentery and to ports that of the size case of such dynentery reviewed at an Army hospital overseas, 32 (14%) were disposed as presenting liver involvement.

The conet of this complication is usually indifices with only anoreus malaise, and vague epigatic distress with the result that the patient may not appear for diagnost until several months after initial attack of districts, and then usually with only low grade fever moderate leuccytosis, an elevated sedimentation rate and tendemoss over the liver without any frank pathognomonic signs on physical examination. For this reason the author believes the associated roentigen changes, if present, may be of considerable help in superstine or chocking the

diagnosis

Of the 32 cases diagnosed as amebic benatitis 12 were examined roent renologically, of these, 10 (45%) showed elevation of the right less of the disphraum In the chest films, and fluorescopy movement of the diaphragm was reduced or absent. In regions where amebic dysentery is prevalent, the author re gards these roentgen findings pathognomonic of ameble liver disease. Secondary compression of markings in the base of the right lung frequently accompanied the disphragmatic elevation and oc casionally there was a little pulmonary infiltration. In a few instances minimal right costophrenic pleuritis and effusion were also encountered which the author believes was due to rupture of a liver abcess into the pleural cavity. Prone abdominal films were not always helpful, but in some cases they did show a downward extension of the inferior hepatic border as related to the costal margin-

repairs borner as related to the continuaging a course of emetine therapy these roentgen signs disappeared but more slowly than the symptoms. In only a very small percentage of cases did anothel liver disease require aspiration.

LIMAN DOMINGON M.D.

Brooke, II. H. W., MacKenzia, W. C., and Smith, J. R.: Pneumoroentgenography with Organ in the Distincts of Internal Derangements of the Knee Joint. Am. J. Reedy. 1945, 54, 462.

The authors used oxygen pneumomentgenography for the diagnosis of internal derangements of the knee joint whenever the clinical evaluation remained inconclusive and the routine reentgen examination falled to help although the symptoms strongly suggested some sort of disability

A total of \$5 cases were examined of which 18 showed positive findings. Ten cases came to operation and in all but 1 the rountgen findings were confirmed. The failure in the tenth case was attributed to insufficient removal of the synovial fluid and in complete failing of the joint cavity with orygen.

The authors give in detail the anatomic and surgical considerations. The procedure must be done in the operating room under aseptic conditions. From roo to 140 cc. is the optimum amount of coryen necessary for good filling. Collodion is spolled to the needle puncture site and then the patient is taken to the roentgen department on a stretcher. Roentgenograms are made in standard pontions. The use of the curved casette holder and multiple stereo projections are however of definite value.

In the interpretation of the abnormal pneumoroentgenogram of the knee joint the following points were found to have diagnostic significance (1) roughening and narrowing of the cartilage surfaces either of the articular surface coverings or of the semilunar cartilages (2) uninterrupted gas columns along the inner aspect of the collateral ligaments of the joint where capsular structure should be firmly attached to the periphery of the menisci (1) in creased density in the intercondular or nonarticular region with a corresponding lack of density in the lateral or medial region of the joint (4) separation of the menucus shadow from the contiguous bone structures (5) calcified and more especially non calcified loose or semiloose bodies (joint mice) (6) narrowing of the joint space and (7) exostosis or churnation of the articular surfaces. The last three findings can also be demonstrated in the routine roentgenograms of the knee,

The conclusion is reached that the method is a useful adjunct in well selected cases. Under aseptic surgical conditions it carries little risk of complications.

Theocorta, M.D.

Coolidge, W D and Charlton E. E.: Roentgen Ray Tubes Radiology 1945 45 449

The authors describe the technological development of x ray tubes from the simple gas discharge tube first used by Roentgen in which the glass wall of the tube functioned haphazardly as the x ray emitting target under bombardment by electrons to the one hundred million volt circular induction electron accelerator tube, which promises to become not only a widely used instrument in medicine and industry but also a source of unpredictable scientific information.

There are essentially 3 groups of x ray tubes I Gas filled tubes, most of which operate with a cold cathode. They are antiquated mainly because of their instability and the impossibility of controlling the current passing through them and of choosing the voltage applicable to them independently from current and gas pressure.

2 High vacuum tubes with a cold cathode (socalled field current tubes) which did not gain ac

explance for similar reasons
3. High vacuum tubes with a hot cathode. This
type of tube is the only kind used extensively today
It was developed by one of the two authors (Cool
idge) whose name it bears. Encouraged by the work
of Langmuir he developed a hot cathode which con

sisted of an electrically heated tungsten filament whereas Lihenfeld tried to solve this problem by introducing an auxiliary hot cathode which produced electrons in a sensite invitor than her bear

duced electrons in a separate ignition chamber Coolidge tubes have now been developed to cover a wide range of usefulness. They vary in size from that of an oil immersed dental tube with a bulb diameter of 11/4 inches and a length of 4 inches up to that of the 1,400 000 volt tube of the National Bureau of Standards which is 12 inches wide and 24 feet long. The effective wave length of the radiation generated in such tubes ranges from 0 00025 Ang strom at 100 000 000 volts to 25 o Angstrom at 1000 volts (A table showing the relationship of the factors is given.) The efficiency of these tubes in creases with the voltage. Whereas at 06 000 volts only o z per cent of the cathode ray energy is transformed into x rays in the target, the measured efficiency reaches 10.4 per cent at 2,350 000 volts (A table showing the wave lengths and the efficiency relation is given also ) The advantages of Coolidge tubes over others are described.

Further technical developments are as follows

For roentgenographic tubes

Development of a rapidly cooling tungsten target brazed into a solid or hollow copper block which in turn is cooled by (r) possessing a large heat capa city (2) with stagnant or circulating air by means of radiator fins, (3) with water and (4) by a spontane ous or forced circulation of oil passing through the back of the target which in turn is cooled by air or other media.

Development of the line focus a rectangular focus which by having a slant of 20 per cent (the angle being made by the target surface and the central x ray beam) appears foreshortened in the useful projection, thus equaling a quare focus. This line focus is able to withstand the 3 fold load of an ordinary focus of the same projected suc. (Values for other angles and curves for load limits are given)

Development of target sizes varying from r to o mm. in diameter for different purposes. The allow able loading varies from about 50 to 600 watts per square millimeter

Development of double focus tubes Tubes having two fool of different size allow rapid changeover from flouroscopy to roenigenography which is necessary for the so-called spot film medical reentgenography and other two purpose raying

Development of a rotating target which allows the constant advance of relatively cold metal to the electron bombardment during a given exposure. In modern rotating target tubes the anode disc rotates with from 3000 to 3500 revolutions per minute. The gain in loading over the stationary target, is then about to fold and is generally proportional to the target speed. (A table for the various speeds and exposure times is given). The line focus principle is maintained in these tubes. Technical difficulties with the target bearings still cust but have been overcome in part by coating the bearing balls with silver or barium.

For thera by tubes

Development of improved cooling of a solid tung sten target which is allowed to heat up to high temperatures. Since an x ray treatment may last for up to an hour the tubes have to be designed for continuous operation (The focal spot is allowed to be larger than for diagnostic tubes.)

Insertion of a beryllium metal window into the glass wall of the x-ray tube for superficial therapy to allow the passage of very soft x rays from x to

10,000 volts for superficial therapy

The use of thick walled pyrex glass for from 200 to 400 ky deep therapy tubes to prevent the occurrence of punctures.

The use of a metal hooded target to improve the electric field distribution. This will not allow the secondary electrons commanding from the target to reach the glass wall and thus cause punctures. The metal hood may be made to include a beryllium window.

Use of the x ray beam "transmitted through the target instead of the conventionally used "re flected beam. This principle is of value for the operation of contact and body cavity tubes. It is a necessary one in the use of supervoltage matchines if the voltage is to exceed several million with several results.

f the peculiar angular distribution of highly pene

trating x rays. (Data for the angular distribution at various voltages are given.)

Development of multisectional tubes for 1,000,000 years in machines which allow a more even distribution of the voltage gradient within these tubes by the see of a number of ring shaped electrodes connected to different intermediate voltages. This principle is of special value in the 4,000 000 volt mobile resonance transformer until in which the tube is urrounded by the transformer coils and the electrodes connected to a number of croil tare.

For diffraction tubes

Use of several windows permitting the simultaneous diffraction or spectrographic study of several specimens. Diffraction tubes operate usually on between 30 and 45 kv and utilize the characteristic radiation of various target metals, e.g. copper and molybelemy.

For all types of tuber:

Development of x ray proof and shock proof tabe housings. This more than anything else enables us to enjoy the use of flexible comparatively safe x-ray equipment without which modern radiology is unthinkable.

Most of the described technical advances were made possible only by the Coolidge tube principle.

Loutit, J. F., and Maunsell K. The Prevention of Homologous Serum Jaundice Brit. M. J. 1945 2759-

Homologous serum jaundice occurs from 40 to 160 days after the introduction of a foreign homologous serum into a recipient. Its occurrence may be acci dental, as in so-called syringe jaundice which is believed to result from the injection of traces of foreign blood left in an inadequately cleaned syringe, it may occur following the deliberate injection of serum or plasma as a transitusion or of convalescent serum given as a prophylactic in measles and mumps or following yellow fever vaccination in which human serum is the suspension medium for the killed virus. As to the accidental variety adequate cleaning and sterilization of syringes and needles has been shown to reduce the incidence of paundice practically to zero When the introduction of serum is deliberate the prevention of homologous serum jaundice is much more difficult. The yellow fever vaccine problem was solved only by giving up the use of serum as

a suspension medium This report deals with the results of the introduction of single sera into a number of recipients and a comparison of the incidence of jaundice in these cases with that in a series of cases subjected only to blood transfusions. Blood was drawn from 99 seps. rate donors under sterile conditions, of these 76 had had no previous known attacks of jaundice 15 had had jaundice apparently from infective hepatitis, for some months to many years previously 4 had had homologous serum jaundice some months previously, and 4 were donors who had contributed the only blood which had been used for transfusion to a man with hematemesis who 6 weeks later de veloped jaundice. Of 98 donors followed up for 4 months 94 had no complaints 3 had bilious attacks r donor had a skin rash and none had jaundice. Of 602 recipients of sera from the 99 donors 573 could be followed none of them reported jaundice but 11 reported billious attacks and 3 reported skin rashes. It is probable that the bilious attacks and skin rashes were nonspecific in both series

For comparison 213 patients who had received whole blood or concentrated red cell suspension were studied over a period of 2 months or more. No case of frank homologous serum jaundice occurred in this series although there was 1 case of jaundice diagnosed as infective hepatitis and 1 case diagnosed as hepatitis without jaundice. The findings confirm the impression that homologous serum jaundice comm only rarely after transfusion with whole blood. This is probably due to the fact that patients receiving transfusions of whole blood alone get homologous material from a few donors only get homologous material from a few donors only

In addition to this follow-up only a cases suggesting a relationship between whole blood transitution and subsequent hepatitis have been found. In these cases blood was received from more than 1 donor (a and 22 donors respectively). It is recommended that for therapeutic and prophylactic purposes the serum used should be from a single individual, or from a few persons only.

JOHN L. LINDQUIST M.D.

Harrison F F., and Miller J K.: The Problem of Hemolytic Streptococcus Carriers in Hospital Personnel. War Med Chic., 1945 8 333

A situation is described in which the occurrence of a postoperative infections in asceptic cases seemed to be related to a high hemolytic streptococcus carrier rate among the surgical personnel. The carrier rate was not effectually reduced by chemotherapy A comparison was made of the incidence of streptococci in the throats of the surgical personnel and of the patients and in the wounds of patients during the winter months of 1944 and 1945. The authors suggest that as a precautionary

measure periodic surveys of the flora of the throats of surgical personnel be made.

WALTER H. NADLER, M.D.

Snell A. M., Wood D A., and Melenberg, L. J.: Infectious Hepatitis, with Especial Reference to its Occurrence in Wounded Men. Gatteenter obsp. 1945 5 241

Infectious hepatitis has currently manfested it self as three more or less distinct discal entities the common epidemic jaundice, pastvaccmal (yellow fever) hepatitis and homologous serum jaundice There is no reason to presuppose any fundamental difference in these conditions, the clinical variations probably being due to the route of inoculation and to the general condition of the affected individual While the supposed relation of the three syndromes is not proved it is generally agreed that all fatal cases of any of the three types have shown a common picture at autopsy namely that of acute or subacute (yellow) atrophy of the Fire?

This report deals with the cases of 33 patients who developed jamidee on an average of 34 days following a wound. All of the patients had received blood and plasma at the time of injury and it is believed that the ensuing hepatilis may have resulted from an interogenic agent contained therein. Twenty are of the patients recovered, the remaining 6 expiring on an average of 1 week after the jumidice was first noted. The initial symptoms at the time of the appearance of hepatilis were short dentical with jaundice. Anoresia nasus, sweet central injuries of the patients of

patients, including the 6 who died, developed marked symptoms and signs of involvement of the central nervous system. Suprisingly, the liver and spicen were rarely palpably enlarged in the early stages of the disease Cephalin-cholesterol flocculation tests were positive in all of the patients at some time dur ing their filmers. Although the studies of the hepatic function were limited to those required by medical necessity all of the studies revealed less deviation from the normal than might have been expected. Essential pathological findings in the liver in the 6 fatal cases consisted of an acute autolytic process which was diffuse and most marked in the central and midzonal areas of the liver lobule. Little evi dence of regeneration or repair was observed in these cases presumably because of their brief and violent course.

There was no endence that the disease had been transmitted by dropbet infection to other patients in the ward. A laboratory worker who funderentially drew up a mentiful of around from a fast case developed a mild form of the disease 10 days later. There is ample evidence that the preacter's phase of hepatitis may be detected clinically in these cases, as in the experimentally produced variety of the disease. In case it was predicted that jaunadice would develop on the basis of two positive explain cholesterod focculation tests on x different days. From this and similar observations it is believed that the explain-cholesterod focculation tests occurs positive long before clinical symptoms develop and is probably the earliest evidence of an impending acute hepatitis to be obtained in wounded

men. The authors could not be certain that these cases of severe hepatitis were due to what has been called homologous serum or transfusion laundice. The incubation period corresponded closely to that seen in hepatitis following yellow fever vaccination and in experimentally produced serum paundice. The aver age course prior to the development of serious symptoms in post vaccinal hepatith is about 26 days as contrasted to 3 or 4 days in this series Two possi bilities suggest themselves as to why the disease should follow so serious a course in the wounded men in this series (1) that the amount of icterogenic material was very much larger than that trans mitted in vaccinal hepatitis or in experimental serum jaundice and (s) that the general autritional depletion of the wounded men makes them especially vulnerable. The latter view seems the more reason ablc.

The essential requirement for the prevention of serum jaundles in wounded men is elimination of the use of blood or plasma containing the leterogenia agent. The practical difficulties of doing this are great. The prevention of fatallities from serum sandice occurring in wounded men must begin with the maintenance of the general nutrition of the patients and the correction of protein and vitamin deficiencies if such exist. Early detection of the pretiertie phase is also a matter of considerable importance as specific treatment may save lives and shorten convalescence. Jone L. Lunguigt, M.D.

Dorgeloh, J. R., and Tuily, P. W.: The Relationship of Boeck a Sercold and Tuberculosis Report of a Case in Which Tuberculosis of the Lymph Nodes was Associated with Festimes Highly Suggestive of Sercold. Arch. Path Chir., 1945 49, 399.

Tuberculosis of a cerrical lymph node was found in a patient exhibiting no cutaneous reaction tuberculin. Portions of the lesion presented caseston with acid-tast bacilli in other area, lowever the histological picture was indistinguishable from that of Boeck's sarcold. It is believed that this case lends additional weight to the argument that sar coldosis, in some instances at least, is an atypical reaction to tuberche bacilli or their product or the same of the same content of the same of the same content of the same c

That this relationship may occur even though bacilli anually are not demonstrable in the leason astrodorsh is substantiated by the occurrence of the organism free "M" reactions of leproay and myorth infections and the generally conceded relationship of attroptococci to rheumatic fever and glomerulone platfits.

Kline, B. E., Miller J. A., Rusch, H. P., and Baumann, G. A.: Certain Effects of Dietary Fats on the Production of Liver Tumors in Rate Fed p-Dimethylaminousobensens. Comm. Eur. 1945, 6

Six groups of 15 rate each were fed o.o. per cent of pollmethylaminosusobenees for 4 months in synthetic diets containing (1) no fat, (1) 5 per cent of corn oil, (2) 5 per cent of corn oil, (2) 5 per cent of corn oil (2) 5 per cent of corn oil (2) 5 per cent of corn oil (3) 5 per cent of corn oil (4) 5 per cent of clard. Then a dye free diet was given for s months. A final limitedence of liver tumors of 25 per cent was produced by the low fat diet, as compared with was not of the cent of the c

These data demonstrate the fact that, in general, pointerly similar solutions is the carcinograde when the diet contains fat they show further that the incidence of bepatomas is higher in rats given a diet containing so per cent corn oil than in those receiving a diet with 5 per cent corn oil. It is, therefore apparent, that the level of the fat in the diet, as well as the type of fat, is important for the formation of hepatic tumors by p-dimethylamilozato-bensene.

Cephalin-cholesterol flocculation tests were positive in all of the patients at some time during their illness. Although the studies of the bepatic function were limited to those required by medical necessity all of the studies revealed less deviation from the normal than might have been expected. Essential pathological findings in the liver in the 6 fatal cases consisted of an acute autolytic process which was diffuse and most marked in the central and midsonal areas of the liver lobule. Little evidence of regeneration or repair was observed in these cases, presumably because of their brief and violent

There was no evidence that the disease had been transmitted by droplet infection to other patients in the ward. A laboratory worker who inadvertently drew up a mouthful of serum from a fatal case de veloped a mild form of the disease 10 days later There is ample evidence that the prejeteric phase of hepatitis may be detected clinically in these cases, as in the experimentally produced variety of the disease. In a case it was predicted that jaundice would develop on the basis of two positive cephalincholesterol flocculation tests on a different days From this and similar observations it is believed that the cephalin-cholesterol flocculation test becomes positive long before clinical symptoms develop and is probably the earliest evidence of an impending scute hepatites to be obtained in wounded men

The authors could not be certain that these cases of severe hepatitis were due to what has been called homologous serum or transfusion jaundice. The incu bation period corresponded closely to that seen in hepatitis following yellow fever vaccination and in experimentally produced serum jaundice. The aver age course prior to the development of serious symptoms in post vaccinal hepatitis is about 26 days, as contrasted to 3 or 4 days in this series. Two possibilities suggest themselves as to why the disease should follow so serious a course in the wounded men in this senes (1) that the amount of icterogenic material was very much larger than that transmitted in vaccinal benetitis or in experimental serum jaundice and (s) that the general nutritional depletion of the wounded men makes them especially vulnerable. The latter view seems the more reasonable.

The essential requirement for the prevention of serum jaundice in wounded men is elimination of the use of blood or plasma containing the feterogenia agent. The precised elificities of doing this are prest. The prevention of fastallites from serum jaundice occurring in woonded men must begin with the maintenance of the general nutrition of the patients and the correction of protein and vitamin deficiencies if such exist. Early detection of the preferred phase is also a matter of considerable importance as specific treatment may have lives and shorten convalencence. Toma L. L'amouter M D.

Dorasioh, J. R., and Tully, P. W.: The Relationship of Bosck a Barcvid and Tuberculosis Raport of a Case in Which Tuberculosis of the Lymph Nodes was Associated with Festure Highly Suggestive of Sarcold. Arck. Path., Chc., 124, 26, 50.

Tuberculosis of a cervical lymph node was found in a patient exhibiting no retaneous reaction to tuberculin Portions of the lesion presented cases tion with acid-fast bacilli in other area, however, the histological picture was indistinguishable from that of Boeck's sarcold. It is believed that this case lends additional weight to the argument that surekidosis in some instances at least, is an atypical reaction to tubercle bacilli or their production.

That this relationship may occur even though bacilli unually are not demonstrable in the lesions of sarroldors, is substantiated by the occurrence of the organism free "ki" reactions of leproy and myrothe infections, and the generally conceded relationship of streptococci to rheumathe fever and glomerulone phrifts. Sugara Kars M.D.

Kilne, B. E., Miller J. A., Rusch, H. P., and Baumann, C. A.: Certain Effects of Dietary Fats on the Production of Liver Tumors in Rate Fed p-Dimethylaminoszobenzene. Cancer Res. 1946, 6

Six groups of 15 rats each were fed o.o. per cent of pdimethylaminocarobenance for 4 months in synthetic dieta containing (1) no fat, (3) 5 per cent of corn oil, (3) 5 per cent of love oil, (4) so per cent of corn oil and. Then a dy elree diet was given for a months. A final incidence of liver tumors of 25 per cent was produced by the low fat diet, as compared with 04 and 35 per cent, respectively when the diet contained 5 per cent of corn oil or oilve oil. When 20 per cent of corn oil or oilve oil. When 20 per cent of corn oil or oilve oil. When 20 per cent of corn oil has fed to the rats, large tumors at this time was 100 per cent. When 20 per cent of Corn oil was 100 per cent. When 20 per cent of Corn oil was 100 per cent. When 20 per cent of Corn oil and was given, the incidence of

tumon at 6 months was 87 per cent.

These data demonstrate the fact that in general, p-dimethylaminosaobenzene is more carchospenis when the diet contains fat they show forther that the incidence of hepatomas is higher in rata given a det containing so per cent corn oil than in those receiving a diet with 3 per cent corn oil. It is, therefore, apparent, that the level of the fait in the diet, as well as the type of fat, is important for the forms tion of hepatic tumors by p-dimethylaminosamentain.

# OBSERVATIONS ON RADICAL SURGERY FOR LESIONS

## ALLEN O WHIPPLE, M.D., F.A.C.S., New York, New York

T is now ten years since an effort (28) was begun to revive previous sporadic at tempts at operating on malignant tu mors involving the ampullar area and the pancreas Since then considerable progress has been made in the evolution of the surgery of this region and organ. It is the purpose of this paper to discuss the factors that have made possible this progress and to call atten tion to mistakes to be avoided and to certain safety factors that have been found to insure a satisfactory result in the several procedures that can be used as indicated by the present ing pathology The diagnosis of these lesions is not discussed in this paper

The phase of surgery of the pancreas deal ing with the removal of islet cell tumors for hypermsulmism-a most interesting chapter in itself—had a determining influence in developing the radical surgery for malignant tumors For it was demonstrated that with the use of silk for ligature and suture material with the delicate handling of tissue that such technique requires it was possible to carry out safely and with little reaction limited or ex tensive excision of pancreatic tissue the pre-cristing dread of the pancreas as a not me tangere was removed and the confi dence of surgeons was increased in attacking

From the Department of Surgury Columbia University New ork.

ί

The history of previous efforts to deal radically with the tumors involving the duodenum the common duct and the pancreas 18 worth reviewing because it emphasizes the grave dangers and the serious complications which deterred surgeons in the past from con tinuing attempts to deal with these lesions It must be remembered that these surgeons dd not Lnow of the advantages of vitamin K blood transfusion and other shock prevention therapy and did not appreciate the signifi cance of the principles of silk technique. HISTORICAL REVIEW

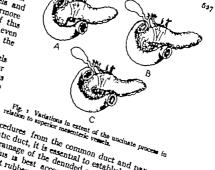

The first successful attempt to remove an ampullar growth with excision of a segment of duodenum and a portion of the pancreas around the ampulla with implantation of the pancreatic and common duct in the line of suture of the repair of the duodenal defect was accomplished by William S Halsted in 1899 His patient developed a stenosis of the common duct after 3 months was reoperated upon a choledochostomy being performed but died 6 months later Autopsy revealed recurrent carcinoma in the head of the pan

Mayo Robson in 1900 and Koerte in 1904 removed cylindrical segments of the duodenum including an ampullar carcinoma but the patients did not survive the procedure In 1907 Desjardins described an operation for

ofk step End to-side gastrojejunostomy is rformed.

oth step. The dilated pancreatic duct is apoximated into the jejunum above the gas jejunostomy a goiter or Carrel rubber tube ing used to connect the pancreatic duct with unal mucosa through a 5 millimeter opening the wall of the jejunum. The rest of the ump of the pancreas is to be tacked to the junal wall with interrupted silk sutures irs. 2 and 1)

IIIk step End to-end or end to-side ioledochojejunostomy is performed depend g upon the use of a loop or a limb of reinum. A posterior layer of fine silk is used r seroscrous suture followed by an over-and ver continuous fine chromic suture to unite se mucosae and walls of the duct and jeju um, followed by the anterior seroserous sture. If there is any tension whatsoever on ils anastomosis the gall bladder or the hepa duodenal ligament should be tacked with iterrupted silk sutures to the jejunal loop or mb to relieve tension. If a limb has been rought up behind the colon the rent in the resocolon should be tacked to the vertical mb of jejunum to close the opening and revent herniation. If a loop has been used for the anastomoses the distal portion should be used for the gastrojejunostomy so as to avoid gastric contents from flowing over the common duct and pancreatic duct anastomoses.

rath step Peritoneal toilet sponge and pad count are made and a careful review of the hemostasis.

13th step The perforated rubber tube with inner suction tube is placed in the subhepatic area away from the anastomoses to collect scenare and leakare of bile etc.

ith ites. Near and far steel were sutures through all layers of the abdominal wall with interrupted fine silk mattress sutures for peri toneum and posterior rectus sheath are placed and tied before the steel wire sutures are tied or twisted to approximate the edges of the incision (Tig 6B). The wire sutures should be left in place for 12 to 14 days. The long segment of each wire suture should be cut at each end near the skin. (Fig 6D). The next day the twisted wire can be removed easily.

It should be emphasized that a slow trans fusion should be started as soon as the patient is found operable and continued during the procedure using if necessary 1000 to 1500 cubic centimeters of blood. It is a long trying operation and depending upon the build of the patient and the presence of fat in the upper

abdomen and mesenteries the time of the pro cedure will vary from 31/2 to 5 hours.

### PRIMARY SUTURE OF NERVES

R. B ZACHAR'S F.R.C.S and W HOLMES, M.A. D.Phil. Oxford, England

HE distinction between a primary and a secondary nerve suture is fairly generally understood, but the precise definition of the terms prents some difficulties. If a time limit is used the criterion for example, suture within 12 or 48 hours, some cases would be wrongly luded from the group of primary sutures though the nerve repair were undertaken the time of the first surgical treatment of wound. In peace time this operation is lly done within a few hours but during the wound excision may not be done for 3 or more days when the direct local ef its of the trauma are still in evidence and re has been no tissue repair. It is clear the environment of a sutured nerve at h a stage is more closely allied to that

h prevails in the immediate posttrau
to period than to the conditions obtaining
the wound has healed and a nerve
to performed in such circumstances
uld still be a primary nerve suture. For the

oses of this paper we define primary suture as the repair of a nerve through original unhealed wound at the time of the rative treatment of the wound itself

ine earliest record of nerve suture is of a ry repair of the median and ulmacattempted by Baudens in 1836 (L&ticnt 1873) Contact of the suture material the nerve was avoided to prevent sams and approximation of the nerve a was accomplished by suturing the

jacent tissues. Unfortunately the patient

1 8 days later and the nerve ends were d to have separated.

I nere is no evidence that the operation was 'ed until nearly 30 years later then in '2 more sutures were reported the first | by Nélaton (Houel, 1864) the by Lauger (1864) Both were print y sutures and in each case it was claimed

Bobnes is Belt Memorial Fellow rom the Department of Orthopastic Surgery (Peripheral ree I jury Centre) and the Department of Zoology and mparative Assistomy University of Oxford. that motor and sensory recovery followed within a few days of operation. Howell and Huber (1893) collected records of 84 primary sutures they concluded that after primary suture the prognosis is favorable. Function will probably be restored completely or They also added that after partially secondary suture the prognosis is good im provement is almost certain and in a large proportion of cases complete success may be expected In comparing the results of primary and secondary suture they were con cerned mainly with the problem of first intention healing of nerves. The view has been remarkably persistent that primary repair of nerves leads to healing by first in tention and early clinical recovery at a rate incompatible with degeneration and regenera tion of the distal trunk, and as late as 1023 at the International Congress of Surgery in London Henrikson reported such a case. But there is no doubt that in all examples of apparently immediate recovery many of which have come under our observation the sensory 'recovery is due to overlap from adjacent nerves and the motor recovery' to anomalous innervation or trick movements the hypothesis of first intention healing is now

emloded. Another review of a senses of primary sutures was that made by Sherren (1908) who examined to cases. Recovery of pain sensibility started between the 5th and 25th week, and touch sensibility between the 19th and 46th week the longer delay was in some cases ascribed to suppuration. He stated that restoration of tactile localization was not as a rule complete until more than 2 years after suture sometimes longer and that all cases uncomplicated by suppuration reguned per fect sensibility He found that motor power returned in about I year after si of the ars ulnar nerve at the wrist and not following suture at the elbow ! Ĭn, specify the quality of reviewing the older cases of

6--

performed at the London Hospital he found only one in which there had been no recovery a patient whose wound became infected Sherren advocated primary suture of divided nerves because the prognosis after secondary suture is more unfavorable

Platt and Bristow (1923) in reviewing the late results of nerve injuries of the war of 1914 1918 refer to the extreme perfection attained after so called primary sutures and the incomplete type of recovery which is the rule in the majority of secondary sutures They ascribe the difference to the type of lesion—the nerve was more seriously damaged in gunshot wounds and these all came into the class of secondary sutures

Gonzalez Aguilar (1928) advocated suture as soon as possible after the myelin remains had been removed from the distar stump at the time when Schwann cells exhibited their maximum activity the optimum time for suture in his opinion is about 30 days after division of the nerve

Herbig (1937) reported a primary inerve sutures; 2 were followed by complete re covery 1 by improvement and there was 1 failure In a series of 13 secondary sutures performed 2 to 12 months after injury, 5 were cured and 8 improved there were no failures His conclusion that primary suture gives the best results does not seem reasonable from

Platt (1937) refers to a series of 12 primary sutures Although he does not give the results in detail he concludes that in primary sutures performed under ideal conditions complete recovery of motor power and re covery of protopathic sensibility at least is to be expected In secondary autures partial or complete motor recovery with imperfect restoration of sensation has been the rule He advocates primary suture in small rel atively clean wounds. In more extensive wounds with widespread bruising and mul tiple tendon injuries and in wounds in which infection has already secured a hold partial or Complete failure after primary suture is almost mevitable

Many other authors (Pollock and Davis 1933 Gallie 1942) hold similar views but Mitchiner (1939) advises primary nerve

suture in gunshot wounds even in the presence of moderate infection

During the Spanish Civil War Jolly (1942) carried out a number of primary nerve sutures but gave up this practice on the advice of Diaz who had found that the results of secondary nerve suture were better

From the accounts of these authors it would appear that the chief factor militating against the success of a primary suture is infection and although many would hesitate to undertake primary nerve repair when in fection is probable few would controvert the statement of Pollock and Davis that if pri mary nerve suture is performed and the wound remains clean and heals by primary intention we have taken advantage of the best possible conditions under which end toend suture may be performed

The investigation of nerve suture by animal experiments performed under aseptic conditions has shown that an optimal func tional result is given by primary suture and that delay in repair progressively prejudices the quality of recovery However the only primary sutures in man comparable with those carried out experimentally are those performed when a nerve is divided either accidentally or deliberately during the course of an operation The conditions prevailing when suture is performed immediately after an incised lacerated or gunshot wound are different in many ways from those prevailing in an experimental or accidental operative section and the following analysis of the re sults of primary repair performed under a variety of conditions has been undertaken with a view to determining the policy to be adopted in the early treatment of divided

## MATERIAL AND METHOD OF INVESTIGATION

Material In this series are included all the cases of primary nerve suture which have come under observation at the Penpheral Nerve Injury Centre at the Wingfield Morris Hospital Oxford during the years 1940-1944 We have excluded all those in which the surgeon arned at nothing more than a rough approximation of the stumps at the primary operation There were 55 primary nerve

ures in 49 patients. In 3 the nerve was liate suture was undertaken. Fourteen were sutured during the primary atment of gunshot wounds and 38 during repair of incised or lacerated wounds the ults in these cases demand special atten

pattern and quality of recovery after n (Table I) suture depend to a certain extent on the involved and for this reason lesions of vidual nerves will be considered separ ly before a final review is attempted.

r variable factor that must be allowed in the analysis is the site of the lesson covery after auture of the median or ulnar rve in the arm is nearly always less satisthan after suture in the forearm and e results in these two nerves are therefore separately for high and low sutures. in the early days of this work those pa whose nerves had been sutured at the imary operation were not subjected to oration unless there was some very reason for doing so such as the of any aign of recovery long after it due Thus the cases in this group have en under observation for a considerable

time-up to 4 years-ample time for recovery to reach a stage at which it could reasonably be compared with that observed after secondary suture More recently after it had been found that a number of primary nerve sutures had not been followed by satis factory recovery the policy was changed and on a number of occasions exploration was undertaken at an early date in 16 cases resection and resuture were performed. In some of the cases subjected to reoperation sufficient time had clapsed for recovery to be apparent and the quality of such recovery as had occurred will be indicated. In a certain number however exploration and resuture were undertaken before any clinical signs of regeneration could be expected and in these the data on which the assessments of the success, or Otherwise, of the primary suture are based are histological-not clinical

Clinical grading of recovery In 1942 the Medical Research Council adopted a scheme for the assessment of recovery in peripheral perve unjuries suggested by Highet (Highet and Irolmes, 1943) This system has a neurological basis, and motor and sensory recovery are considered separately scheme provides a valuable foundation it has been found necessary for our purposes to introduce certain intermediate grades in the assessment of ulnar median and radial palases. For example after a high leason of the median nerve the recovery of slight power in the long flexor muscles is described as grade MI yet another patient who shows con siderable strength in the long flexors but has not yet regained voluntary power in the thenar muscles comes into the same low category Similarly with the ulnar nerve a patient who has recovered only slight volun tary power in the hypothenar muscles is classified as grade 2 which is the grading for another patient who has regained voluntary power in all the intrinsic muscles though not sufficient to act against resistance. It is necessary to introduce intermediate grades for each nerve and the following system has been adopted in this paper. It is presented at length herein since others may find the classification of use in the accurate assessment of recovery

### ULNAR NERVI

M.o No contraction in any muscles My Return of voluntary power in the proximal iong flexor) muscles although they are not able to act against gravity

M 1+ The Proximal muscles act against gravity M 2 The proximal musics are acting and there is a contraction in the hypothenar muscles at least to a contraction in the hypothesia influence at least with either no action in the interesses or not more than a flicker

Ma+ The proximal muscles and the intrinsic muscles are all acting and the first dorsal interosmuscles are an acting and the mat mouses interessed secons muscle produces a definite movement but does not act against resistance

of act against remarkers

## RADIAL MERVE

Mo No recovery Molor Recovery

Mr. Return of voluntary power in the proximal of t Actual or Voluntary power in the proximal muscles but not sufficient power to act against

M 1+ Return of power to the proximal muscles At 1-7 Keimin of power to the proximal muscles sufficient to act against gravity no return in the

M 2 Return of voluntary power in the proximal At 2 Return or voluntary power in the proximation muscles and the muscles acting on the thumb but the state of the state o muscles and the muscles acting on the musil but the latter are not able to act against resistance. M 3 Recovery to M s but abductor pollicis longus and extensor pollicus longus act against re sistance,

M.4. Proximal and distal muscles are acting strongly against resistance and some independent to vention of the impers is possible.

A.4. Independent movement very good but not Perfect. M 5 Complete recovery

Intermediate grades as for median nerve may be used.

Although both motor and sensory recovery will be indicated in the tables giving the results of primary suture it is clear that for the ulnar and radial nerves motor recovery is the more important and should be used as the chief criterion for comparison, whereas for the median nerve good sensory recovery is of chief importance

One further point must be made clear before presenting the results Previous au thors have been impressed by the poor quality of recovery after secondary nerve suture as compared with primary which is not sur prising if all secondary sutures are taken into account. Such a comparison is not of great value since it would include consideration of many nerve injuries for which primary suture would have been quite impossible for ex

ample those in which there was a large gap It would also include many cases in which there was an unnecessarily long delay for example in cases in which exploration had been postponed many months in the hope of recovery because at the primary operation the nerves were not seen to be divided and also in cases complicated by prolonged sepsis Such delay leads to profound changes in the nerve, the end-organs and muscles, changes which adversely affect the quality of re covery A better idea of the value of primary

suture is obtained by comparing the quality of recovery with that seen after early secondary repair of lesions in which the gap was not so

large that it would have precluded primary suture. Some arbitrary classification must be made both as regards extent of the gap to be closed and the interval that elapsed before suture For purposes of comparison we have thought it reasonable to use those secondary sutures performed within 6 months from the date of injury in which the gap was less than 6 centimeters. There must be few wounds in which primary nerve suture is feasible which are not fit for the secondary operation within six months.

### RESULTS

### Clinical Review

a Clinical review of results of primary nerve suture-High ulnar sutures (Table II) The quality of recovery after prunary auture of the ulner nerve above the elbow was not good but recovery of power in the intrinsic muscles of the hand is usually poor after high lemons. whether suture is performed early or late. In 2 of the 6 cases (1 and 3) the final stage of recovery had been reached-in Case I the result was moderate and in Case 3 poor

Low ulnar nerve sutures (Table III) There were 20 cases in which the ulnar nerve was sutured in the forearm at the primary opera tion. In Cases 22 to 26 resection and resuture were performed before any appreciable recovery could have been expected. In Case 21 suture was of the sensor, division only and one patient (Case 20) drowned before there was time for recovery to be well advanced.

The remaining 13 cases had sufficient time to show a considerable degree of recovery Of these 2 (Cases 7 and 8) reached grade M.4 in which some independent lateral movement of the fingers was possible. One was a boy aged 7 years which is significant since it has become clear from a study of many nerve in juries that the rate of recovery is more rapid and the quality better in children than in adults. Two others reached grade M 3 Three patients recovered to grade M 2 In one of these an anomalous branch was found arising above the lesion and joining the nerve again below the site of division. The sparing of this branch might have enhanced the qual ity of recovery In Case 13 the primary suture was performed at the Wingfield Morris Hospital and the lesion was re-explored 19 months later because recovery was not proceeding satisfactorily. There was a large neuroma at the site of suture.

In the remainder the recoveries were poor although in Cases 14 15 and 16 the assessment must not be regarded as final.

Median merce sutures (Table IV) There was only one primary suture of the median nerve

degree sufficient to localize the stimulus and to distinguish the points of a compass less than i centimeter apart. One of the patients was a girl aged 5 years. In 3 others two-point discrimination and localization did not return so well but there was no over reaction to pun prick. In Casea 35 and 36 there were moder ate sensory recoveries but in the remaining 5 recoveries were poor although further im provement might occur in 2. In 6 patients (including 2 mentioned above) the site of primary suture was explored and secondary suture undertaken. They will be considered later.

Radual nerve sutures (Table V). There were 7 cases of primary suture in 5 sufficient time had elapsed for some degree of recovery to be apparent in 2 re-exploration and suture were performed at an early date

Of the 5 I showed good recovery, I moder ate, and 2 fairly poor the last 2 may improve further since they have been followed for only 15 and 18 months respectively there was one failure

Sciatic nerve sutures (Table VI) In 3 patients the posterior tibal nerve was sutured at the primary operation with recovery of touch and pain sensibility but persistence of overreaction to pin prick. There was only I

patient in whom the main trunk of the sciatic nerve was sutured at the primary operation. The site of suture was explored and resected before recovery could have occurred and this case is considered in the histological section.

There were no primary sutures after wounds involving the lateral popliteal nerve

b Comparison of results of primary and early secondary sutures. The results of primary and early secondary sutures of the ulnar nerve above the elbow are shown in Table VII Most of the gradings are not final but it does not appear likely that the results of the final comparison will be significantly different. In none was there motor recovery to grade M 3

Low ulnar nerve sutures (Table VIII) have good and poor results in both groups, but it is clear that the general standard of recovery after secondary suture is better than after primary suture. Two out of 13 primary sutures had reached grade M.4 compared with 4 out of 12 secondary sutures. Four primary sutures had reached the stage at which the intrinsic muscles were acting against resistance (M 3) whereas 8 secondary sutures had reached this grade. Although there are 3 primary sutures in which furthe progress is likely 4 secondary sutures shoul improve still further.

Three of the 9 secondary natures of the median nerve (Table DA) reached a high grade of recovery compared with 3 out of 13 primary sutures. Six out of the 9 had reached grade S 3 compared with 6 out of 13 primary sutures. The contrast between these two groups is not striking but the balance is in favor of the secondary sutures. Four of the latter have not yet reached their final stage and 3 primary sutures may show some improvement latter.

The high quality of recovery after early secondary suture of the radial nerve is at once apparent (Table V) Six out of 8 secondary sutures reached grade M.4 compared with

one out of 5 primary sutures. Further improvement is likely in 2 accordary antures and also in 2 primary sutures. Allowing for the recovery of these sutures to the next grade, the belance would still be strongly in favor of the early secondary sutures.

Two early secondary satures of the posterior tibial nerve resulted in recovery of a similar grade to that after primary sature, but the value of comparing recoveries of this nerve is probably not great, on account of the difficulties in grading sensibility on the sole of the foot.

The comparison between recoveries after primary and secondary nuture is set out in the instograms (Figs. 1 a, 3) in which the motor or sensory recovery is plotted along the abscuss and the number of cases is plotted along the ordinate. The method has limitations afnor the time interval after suture is omitted, but an indication is given of the cases likely to above further recovery i.e. where the assertment was made less than six hundred days after operation.

Now that the data in each group have been presented we can depict the results in the whole clinical series in the form of a single composite histogram. For this purpose we have recorded the motor recovery of the ulnar and radial nerves and the sensory recovery of the median nerve on the same histogram. The result is shown in Figure 4 in which the more uniformly good results after early secondary suture are at once apparent. The number of recoveries to grade M4 or S3 after secondary suture is r6 out of 34 with 7 intermediate re-

of other recovery probable.

coveries of lower quality. In the group of primary sutures 9 out of 39 had reached the same high grade with 9 other recoveries at an intermediate stage. However even in the incomplete recoveries the quality is higher in the early secondary sutures 9 out of 11 intermediate recoveries in the early secondary sutures had reached M 2+ or S 2 whereas none of the corresponding primary sutures had recovered so far

c Associated factors. Why do these results not bear out the theoretical superiority of primary nerve suture over later repair?

What adverse factors may have impaired or prevented recovery?

Age Two primary sutures were performed on children aged 7 and 5 years respectively (B.40 and 0 10) and both resulted in a high grade of recovery The influence of youth on the quality of recovery is shown by another case not in this series. A girl aged 9 years sustained a division of the median nerve which was repaired 3 years later. Eighteen months after operation there was recovery to M.4 S.3+ equal to that of the best primary suture. There were no children in the group of early

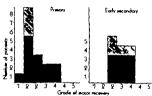

Fig. Histogram showing recovery after primary and early secondary sutures of the ulnar nerve. In all histograms cross hatched area indicates intermediate grade of recovery; black area final grade of recovery

secondary sutures and with this exception, the ages in the two groups are comparable almost all being between 20 and 40. The results in this group of primary sutures have been enhanced by the inclusion of these two children.

The type of injury Of the 14 gunshot wounds in which primary suture was per formed, 12 had sufficient time to show recovery Three of these reached a high grade M4 or S3 and 4 others in grade M 2 or S1 may atill improve (Fig. 8).

Twenty-seven lacerated and incised wounds, aimilarly treated, showed 6 good recoveries (grade M.A. or S.3) and 5 in the lower groups

may improve still more

There is no conclusive evidence from these figures of any clear superiority of primary nerve suture in lacerated and incised wounds over that performed in gunshot wounds.

Sebiss Three primary sutures were fol

lowed by gross sepsis and at operation the

Karther property reshalls

came infected were eliminated. Although the results are better than when the infected cases are included, there is still a considerable proportion which have not reached a high grade of recovery.

Physical trealment The two principal types of physical therapy which may have in fluenced recovery—and so far as we know only motor recovery—are passive movements to preserve joint mobility and electrical stimulation of the paralyzed muscles. The first is irrelevant since only 1 patient (P 21) had limited mobility of the joints of a degree sufficient to interfere with the function of the recovering muscles.

The influence of electrotherapy on the quality of recovery is very difficult to assess Only those cases are available for comparison in which motor recovery is the criterion namely ulnar and radial pulsies. I our teen out of 21 received electrotherapy but the intensity frequency and duration of the treatment varied between such wide limits that it would be unreasonable to place too much reliance on the pooled results and in any subdivisions the numbers which were included in each instance would be statistically insignificant.

The histogram (Fig. 7) shows no evidence a significant effect of galvanism on the qualit

of recovery in these primary sutures

It is clear that the factors we have
discussed do not fully explain the failure of
such a large proportion of primary in
sutures to reach a high grade of recovery.

Ao arms are visible in the distal apposition.

string material. An arous are vision in the dutast bundles, which they would undoubtedly have reached after 4 weeks had the string been successful. A poor union as a result of faulty

Spontion.

CASE 44. R.60. May 22 1944 patient received a laceration of the right foreign with division of nection of the right success while coloring median and nimer nerves. Primary source of nerves was done within 5 hours. September 8 10st, parties was admitted to the Wingfield-Morris Hospital. No recovery September 9 1944 operation was performed under local anathesis. The median nerve was surrounded by dense sear the neurona measured 27 by 0 6 by 1.0 centre was the measured. Trial section revealed only one food bundle. Re section and resulture were performed.

Histology The gap separating the proximal and dirtal bundles is amail, but the intermediate zone country latters of quite matter of collates with comments ungery or occurs masses or causages with a some agreement of inflammatory cells. Through this scar tissue there has been only slight reunion of time scar these there has been only sugar remnor of the stimps and the distal frunk contains no mye tor stange and the times and a contain or my limated fibers some of the buildles contain many

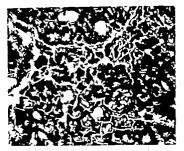

Fig. 8. Case 33 Detail of the endoneurium in a nerve bundle about 8 millimeters distal to the suture line. Most of the Schwann tubes are very small in diameter and are surrounded by dense blocks of collagen. Masson, ×645

axons, but others few or none The endoneurium of the distal bundles shows an excess of collagen im mediately below the suture line Conclusion A poor reunion with grossly excessive

scarring between the stumps

CAST 30, S5 5 June 20 1042 patient suffered a
laceration of the right forearm. Operation was done
within a few hours. The median nerve was found
divided in the middle third of the forearm. It was
sutured with fine sulk after trimming. Plaster was
applied with the elbow fiexed go degrees and wrist
fexed 45 degrees and maintained for 2 months
August 25, 1042, patient was admitted to the
Wingfield Morris Hospital. Complete median para
lysis below branches to long flexors. Daily physiotherapy started including galvanism to the thenar
muscles. July 5, 1043, the only signs of recovery
were a flicker in abductor pollicis brevis and a slight
decrease in the area of auslgesis. Operation was

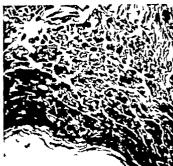

Fig. 9 Case 23 Detail of the endoneurium in a bundle about 6 millimeters distal to the suture line. Similar to Figure 7 but the endoneurial collagen is even more dense, and the Schwann tubes hardly distinguishable. Marson, Xô7o.

performed and a neuroma measuring 2 5 by 1 5 by 10 centimeter its proximal part soft but the distal portion very firm was found. Stimulation produced a motor and sensory response but in view of the consistency of the lesion it was decided to resect and resulture

Histology The lesion consists of a fusiorm awell img composed largely of nervous tissue. The proximal and distal bundles are connected by tissue consisting of abundantly reinnervated. Schwann tubes (Fig. 33) with only slight excess of connective tissue. The distal bundles are uniformly innervated by small myelinated fibers (Fig. 15) except for half of one bundle in which myelinated fibers are as numerous at the forent. Myelinated fibers are as numerous at the

- 3 Scar between the nerve ends The amount of scar tissue between the sutured stumps was variable but in several cases greatly excessive and clearly hindering re generation
- 4 Excessive endoneurial fibrosis was frequently noticed particularly in the distal stump immediately below the suture line. In some cases it was so excessive that satisfactory regeneration would have been immossible.
  - 5 Separation of the sutured stumps.
- The first two faults are due to poor tech inque in which the suturing has been mac curate. The third and fourth are probably due to inadequate excision of the damaged nerve ends. This can hardly be classed as faulty technique since the fibrosis between and within the bundles would not be present at the time of the primary operation and we do not yet know how to recognize macroscopically the changes that will lead to excessive collagen formation within the nerve stumps. It is also possible that excessive postoperative tension on the nerve could be held responsible.

The separation of the autured stumps may be due to unduly rapid extension of the joint which was flexed to approximate the nerve ends or else due to excessive tension at the time of operation or possibly sepsis. But of the 6 cases in which separation occurred

Fig. 15 Case 30 Part of a nerve bundle in transverse section at the distal end of the specimen, showing the condition of the nerve fibers below the suture line. Myelin sheath stain. X560.

there was only 1 in which the extension of the joint had been unduly rapid (Table XI) Sepsis was present in only 2 cases and undue tension at operation must be considered to be the cause of separation in the other sutures

### DISCUSSION

The first conclusion arising out of these records is that contrary to the widely accepted view the best results of primary nerve suture do not approach nearer to perfection than the best results of early secondary suture Indeed, considering only those cases in which there has been adequate time for recovery the proportion of good results is higher in the early secondary sutures in this series. The scales are weighted still more against the primary sutures if we take into account those in which re-exploration and

there was only 1 in which the extension of the joint had been unduly rapid (Table XI) Sensis was present in only 2 cases and undue tension at operation must be considered to be the cause of separation in the other sutures.

### DISCUSSION

The first conclusion arising out of these records is that contrary to the widely ac cepted view the best results of primary nerve suture do not approach nearer to perfection than the best results of early secondary suture Indeed considering only those cases in which there has been adequate time for recovery the proportion of good results is higher in the early secondary sutures in this series. The scales are weighted still more against the primary sutures if we take into account those in which re-exploration and

Fig. 16. Case 51. The specimen in longitudinal section, howing the site of suture. P Proximal nerve bundle D dutal nerve bundles. X4.

planation for the failure of so many primary

autures to reach the expected high standard? It has been all too readily assumed in the past that if infection can be avoided after primary nerve suture the result should be

good Although in a few of the cases recorded above sepsis may have been an ad verse factor there are many in which the wound healed without sepsis and yet the

We have no evidence that the results in this group of primary sutures have been un lavorably influenced by lack of physical therapy Indeed, an unduly favorable effect has probably resulted from the inclusion of two children in the series. We must, there fore assume that the quality of surgical repair which is possible at the time of the primary operation is a factor of considerable importance The standard of surgery de pends on the experience of the surgeon the facilities available for good surgery and the condition of the injured tissues

It might be suggested that it is unfair to compare primary autures performed by aur geons of all types with secondary sutures performed at a nerve injury center by men experienced in nerve repair. However many of the primary sutures which have failed were performed by experienced surgeons. More over after one of the primary sutures under taken at this nerve center a case in which there were no complicating factors, the results were not good. Furthermore primary wound treatment in peace or war is not usually performed by senior surgeons and tre think it likely that we have in this series a airly representative selection of the work of

those surgeons who are normally faced wit the problem of primary nerve suture. It min be noted that we have excluded from the series three examples of gross error at the time of primary nerve suture when a nerve

Nearly all the primary sutures were under taken at hospitals in this country in which the facilities for such emergency work are ade

In our opinion the chief adverse factor in primary suture is the difficulty in recognizing how much of the nerve has been damaged on each side of the site of division, with the result that resection is often inadequate. On the other hand if the resection is satisfactory there is the risk of excessive tension at the site of suture since extensive mobilization of the nerve is never performed in a fresh wound After 3 or 4 weeks the intraneural connective tissue changes are sufficiently obvious to indicate the amount of nerve to be resected, and there is the additional benefit of thickened nerve sheath which facilitates auture and makes the suture line more stable the epi neural stitches are less likely to pull through such a aheath than they would through that of a freshly divided nerve

One further objection to the selection of cases in this series might be that only those primary sutures which were not progressing favorably would be sent to a nerve injury center many good results would thereby be mused. There are two anappers to this objection first by arrangement with the medical departments of the three services, all cases of peripheral nerve injury are referred to appropriate centera Second it is seldom possible to be sure within 6 months of the

date of suture whether the final result is likely to be good or not. We have ourselves found this difficulty even after sutures at the level of the wrist Thirty six out of the total of 40 patients were referred to us earlier than 6 months after injury (Fig. 17) and it cannot, therefore be accepted that we have had an undue proportion of those in whom the result was known to be poor

### CONCLUSION

The results set out in this paper raise im portant questions of policy in the primary treatment of divided nerves. In the usual civil or industrial laceration where one can expect wound healing within a few weeks primary suture may give a good result, but one can be more certain of a high grade of recovery after an early secondary suture. However there is nothing to be lost and indeed a great deal to be gained by approximating the ends of the divided nerve to prevent retraction. When secondary suture is performed in a few weeks the length of nerve to be resected will probably be short the suture can be performed with precision and without tension and the prospects of recovery will be good. If deliberate primary suture has been performed the patient should be watched carefully for early signs of recovery and if they are lacking or progress appears to be unduly slow re-exploration should be under taken without delay and further resection and resuture considered

In war wounds the local damage to the nerve ends is likely to be more extensive and the chances of performing an adequate excision of damaged nerve trunk and accurate epineural auture at the primary opera tion are not so good. An early secondary suture is more reliable. Here again primary approximation of the nerve ends is im portant and with adequate wound surgery and the latest adjuncts to prevent sepais and encourage wound healing the secondary operation should be possible within a few weeks or at most a few months. Although we have arbitrarily chosen a limit of 6 months for early secondary sutures we are convinced that, even within this period, the earlier the suture is undertaken the better

We can sum up our views as follows Formal nerve suture should be undertaken at the earliest moment when it is possible to recognize the extent of damage to the nerve excise the injured segment and bring together the mobilized nerve ends without the prospect of undue postoperative tension

### STHWARY

- The results of 55 primary nerve sutures are presented and compared with results of a series of early secondary sutures
- 2 There was a higher proportion of poor recoveries and a lower proportion of good recoveries after primary suture
- 3 Sepsis was not the chief adverse factor involved
- 4 The histological examination of the site of primary suture in 16 cases indicated that the chief faults were poor technique inadequate resection of the damaged nerve ends and excessive postoperative tension
- 5 There is a better prospect of a good recovery after an early secondary suture than after primary suture
- 6 Primary approximation of the divided nerve stumps is always advisable

## A CLINICAL AND PATHOLOGIC STUDY OF THE KIDNEY IN PATIENTS WITH THERMAL BURNS

W.E. GOODPASTOR M.D. S. M. LEVENSON M.D. H. J. TAGNON M.D. C C LUND M.D., F.A.C.S. F. H. L. TAYLOR, Ph.D. Boston, Massachusetts

MPAIRMENT of kidney function as evidenced by persistent oliguria and elevation of the nonprotein nitrogen in the blood is a frequent early complication in the course of patients with severe thermal burns. (9,34) companied by albuminum and urmany casts (34) A few descriptions of the morphology of the kidneys in patients dying with burns have been published (9 to 23 34) the most consistent findings being the following-on microscopic examination the glomeruli are usually normal while the tubules show vary ing degrees of necrosis affecting principally the convoluted part Pigmented casts have also been observed in the tubules. These have been considered to be hemoglobin casts although direct proof of this is lacking Some support to this conception of the nature of the casts is lent by the occurrence of hemoglobin oxyhemoglobin and methemoglobin in the blood and urme of severely burned patients (23) In none of these reports however has there been an attempt made to correlate the clinical and pathologic findings study based on 47 patients with fatal thermal burns admitted to the Boston City Hospital during the period from November 1942 to July 1944 is presented here Additional data on patients who were admitted and survived during the same period will be presented else

In the following study the area of burn was catimated by the method of Lund and Brow

Those the 11 likey logistate of Pethology, the Thorodal Language of Security of Pethology, the Thorodal Conference of Security and Day Security of Security of Security of Security and Day Security of Securit

der The depth of burn is described according to the new method of Converse and Robb-Smith. They classify burns by name instead of number using the terms epidermal for so called first degree burns, dermal and deep dermal for accound degree and deep for third degree The area of epidermal burn was disregarded. The extent of the deep burn cannot be determined with accuracy in patients who survive for only a few days. For this reason the extent of deep burn in such patients can only be estimated. Associated respiratory tract injury was graded from 0 to 4, depending upon the extent of injury to the respiratory tract found at autopsy

The local treatment of the burns varied. During 1942 triple dye and tannic acid-silver ntrate were most frequently used, while during 1943 and 1944 the most frequent me thods were pressure dressings or casts, dry or with a bland ointment Morphine was usually given two or three times in the first 36 hours. in doses of 14 grain for adults and correspond ingly smaller doces for children. In a small number of patients phenobarbital or pentobarbital were used for sedation Most patients with burns involving more than 10 per cent of the body surface received intravenous infu atons of citrated plasma or serum. The plasma contained dextrose in amounts varying from

10 to 17 grams for each unit of 250 cubic contimeters. Some contained merthiolate in a final concentration of 1 10 000 as a preserva tive Many patients received transfusions of type specific citrated whole blood A small open and contact make the property of patients received intravenous injections of a 25 per cent solution of human albumin. Thu also contained an organic mercurial 1 10 000 as a preservative Sodium lactate was given intravenously to some patients in the form of a molar aqueous solution and others were given sodium bi carbonate by the oral and intravenous routes.

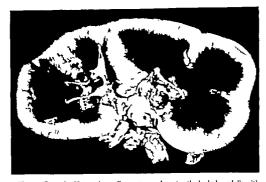

Fig. 1. Case 18. Note pale swollen cortex and contrastingly dark medulla with dark lines converging toward papillac. These lines in fresh tissue are black and histologically prove to be tubules containing blood pigment casts.

Intravenous glucose and isotonic salt solutions were also given to most of the patients.

In the evaluation of kidney function the following signs were considered to constitute evidence of lasting impairment-persistent azotemia with a level of nonprotein nitrogen exceeding 40 milligrams per 100 cubic centimeters of blood and oliguria or anuria per sisting beyond the period of shock. Periods of transient azotemia and oliguria occurring only during the period of shock or terminally or associated primarily with heart failure were not considered evidence of lasting renal dysfunction due to the burn The plasma non protein nitrogen total protein and albumin determinations were carried out by the routine methods as given by Peters and Van Slyke In patients receiving sulfonamides (chiefly sulfadiazine) the blood levels of the drug were determined at regular intervals Hemoglobi nemia was detected by examination of the supernatant plasma in the hematocrit tube The icterus index was estimated by the method of Murphy

Hemoglobinum was detected by the red or dark red appearance of the urme in the absence of gross hematuria. In most cases the diagnosis was confirmed by a gualac or benzidine test. In some cases the qualitative reaction for detection of hemosiderin with ammonium sulfide was carried out. The urine was usually tested for acidity or alka linity by litmus paper but occasionally more accurate estimation was made with nitrazine paper.

Shock was recognized by the usual clinical criteria of fall in blood pressure rapid thready pulse clammy extremities. An attempt was made to grade the severity of shock according to intensity and duration. The following criteria and qualifications were used for grading o patients who were never in shock for a period not exceeding 1 hour 2 patients who were in shock from 1 to 4 hours 3 patients who were in shock for longer than 4 hours or were in shock on more than one occasion. This last group includes also all patients who died in shock.

Morphologic examination of the kidney was done on sections fixed with Zenker's fluid and formalin and stained with phloxine methylene blue Lee-Brown modification, of Mallory's anline blue stain sudan IV for fat and a modified van Giesen stain for hemoglobin described by Dunn and Thompson With this last method hemoglobin casts in the kidney stain varying shades of green In our

### OBSERVATIONS

# Renul Morphological Changes

Twenty of the 47 patients showed definite morphologic changes in the kidney at autopsy In 2 cases the renal lesion was acute pyelone phritis, entirely different from the lesions in the 18 other patients. In these latter pa tients the changes were all similar and consisted chiefly of the presence of tubular casts and degeneration and necrosis of the tubular epithelium (Figs. 1 to 7)

I Tubular casts Tubular casts were found in all 18 cases and were made up of (1) pig ment, and (2) desquamated epithelial cells. A maximum of 50 per low power field were found (Fig 2) Casts composed largely or exclusively of pigment were most numerous. Casts composed entirely of epithelial cells were rare Morphologically the pigment casts had a fine or moderately coarsely gran Most often the granules were approximately the size of red ular structure (Fig 3) crystal like green or blue cast particles were blood cells, or smaller

sometimes found The color with phlorine methylene blue stain varied from red to orange, brown green and blue The blue color was most frequent although all the other colors usually could be seen in a single section A positive staining reaction for hemoglobin in the casts was observed in all 17 cases in which this procedure was carried out. These casts were observed exclusively in the ascending and descending portions of the loops of Henle and in the collecting tubules. number was found in the medulla (Fig 2) although some could also be seen in the cortex Identification of the tubule involved was impossible in some instances because of the presence of degenerated epithelium adjacent to a cast. The epithelial casts were made up of necrotic tubular epithelial cells, although pigment particles were usually present also (Fig 6) These casts usually were acidophilic with phloxine methylene blue stain stained by the method of Dunn and Thomp-

son for hemoglobin the cell debris stained red and the particles of pigment when present green The staining reaction and the very fine granularity of the cell debris were similar to that of the cytoplasm of easily identifiable intact degenerated epithelial cells In an occasional cast infiltrating monocytes and polymorphonuclear leucocytes were seen Fibrin deposits in tubules were small and rare 2 Degeneration and necrosis of renal tubules

This change was found in two sites, i.e. in convoluted tubules and about casts lying within distal portions of the tubules. The degeneration and necrosis in these two sites seem to be distinctly different.

Necrosis and degeneration of convoluted tubules was found in 7 of the 18 patients. The cells were swollen pale and granular In some instances the cytoplasm was vacuolated in others the cells were partially or com pletely disintegrated so that individual cells could not be defined and the lumens of the tubules were filled with disintegrated cells (Figs 4 5 7). The nuclei were often pyknotic or absent. There was no correlation between the number of pigment casts and the extent of tubular necrosis. In each instance the kid neys described as having tubule necrosis or degeneration also showed indirect evidence of

the antemortem nature of the changes by the presence of one or more of the following-regenerating epithelium mitote figures indicative of tubular regeneration and casts in the datal portion of the tubules composed of descummated negative initialist cells.

Tubular necrosis adjacent to casts were seen in 12 cases. The necrosis was limited to the cells surrounding casts. The cells were not swellen, pale or granular but were deeply compositile. Nuclei were pyknotic or absent In many instances the cells had become separated from the basement membrane and incorporated into the cast About some casts no cells were seen and only the basement resolvance of the tubules pressured.

3 Regeneration of epithelium Regenerating epithelium was found in 7 cases. Its presence is indicative of repair of tubular necrosis. In some cases necrosis was demonstrable along with regeneration. In others, actual necrotic

cells were no longer present.

Regenerating epithelial cells in the presence of necrotic cells were flat and basophilic lying against the basement membrane. In contrast, the cosinophilic, pale, granular necrotic cells often overland the regenerating cells (Figs. 4,5). Mitotic figures were usually not nu merous (Figs. 4,5,7). Cells with mitotic figures were usually large cells which protruded prominently into the lumen (Fig. 5). In tubules winch were composed entirely of recently regenerated epithelium and from which the necrotic cells had disappeared, the lumen appeared large because of the flat lining epithelium (Fig. 7). Mitotic figures in these less actively regenerating tubules were lever

4 Gross pathological changer. In contrast to the microscopic examination gross examination of the kidney revealed abnormalities in only 5 cases. In 3 cases the medulla had adrik red appearance and presented prominent black, brown, or purple-red streaks converging toward the papillac. The dark streaks in the pyramids correspond to the tubules filled with pigment casts. In 4 cases the cortex and the zone of the medulla included between the pyramids were definitely paler and more swellen than normal (Fig. 1). This appearance was considered due to the inbulled descentation. In 2 cases, the kidney

weights were significantly higher than normal whereas in all other cases the weight of the kidneys approximated the upper limit of the normal value or was only alightly increased. In 2 cases unidentified orange crystals were seen. Small areas of hemorrhage were seen in the mucosa of the pelvis in 4 cases. In 1 case a similar area of hemorrhage was observed beseath the mucosa of the ureter

5 Classification of the patients according to the morphological changes. For the numore of analysis, the 42 patients are divided into two groups on the basis of the autopsy findings. Group I comprises those in whom definite morphologic abnormalities were found in the kidneys while Group 2 is made up of those in whom no definite anatomical changes were found in the kidneys. Group 1 is composed of 20 patients and group 2 of 27 patients. Three patients in group a who died within 6 hours after injury are considered senarately since they differed markedly from the others in extent of deep hurn, severity of shock, clinical course, and early death. Two patients in croup a are also considered apart since the morphologic abnormalities observed in their kidneys were probably not directly related to the burn. In both of these patients the renal lesion was that of acute nvelonenhrits and was different from the renal lexions observed in the other 18 cases in group 1

In the following discussion, the patients in group I (with the exception of a patients) will be contrasted with the 24 patients in group 2 who survived longer than 6 hours following

injury

#### Read Function

A striking contrast between the two groups appears when the renal function is considered. The elevation of nonprotein nitrogen was higher in group 1 than in group 2. Two group 1 cases had nonprotein nitrogen levels above 150 milligrams per 100 cubic centumeters and 7 others had levels above 80. In group 2 only 3 patients had levels as high as 80. The high elevation was more constant in group 1 things of the former cases on which data are available had an elevated level commencing abortly after injury and persisting to death. Among the

group 2 cases, 15 of the 24 patients had an elevation at any time and 3 of these elevations occurred late in the course In most of the remaining group 2 patients the elevation decreased to normal before death after an early elevation

Oliguna of a persistent nature was pres ent in 7 of 11 patients of group 1 surviving longer than 2 days. All patients in this group who died within 48 hours also had oliguria. In contrast oliguria was observed in 6 pa tuents of group 2 and in 5 of them it was limited to the period of shock. In the sixth patient the oliguria was associated with cardiac failure

Examination of the incomplete data on specific gravity of the urine does not show a clear correlation between the amount of retention of nonprotein nitrogen in the blood and the ability of the kidney to concentrate or dilute urine.

A comparison of the amounts of nitrogen excreted in the urine by the patients of the two groups is difficult because determinations of daily urmary nitrogen were not carried out in all cases and because of the differences in ime of survival after injury between the two groups of patients. However the available data suggest that there was, on the average a higher output of urinary nitrogen in patients of group 2 than in patients of group 1 This is rendered more significant by the fact described above that the blood nonprotein nitrogen level was more elevated in group I than in group 2 Data on urinary nitrogen as compared to the blood levels of nonprotein nitrogen in 2 of our cases illustrate this point.

Urine reaction Eleven of 13 patients in group I on whom the initial reaction of the urine was tested had acid urine In the 2 other cases, it was neutral Two had alkaline urines subsequently in the first 24 hours. In group 2 the initial reaction of the urine was tested in 13 patients and found acid in all except 3 It was alkaline in 2 cases and neu tral in the third Subsequent samples of

urine were acid in most cases. Other findings in the urine. Granular and hyaline casts were found in the urine of 9 patients in group 1 and 4 in group 2 Protein was present in significant amounts in the

urine of 15 patients in group 1 and in 12 pa tients in group 2 Significant numbers of red and white cells were found occasionally in the urine of 13 patients and repeatedly in the urine of 5 patients in group 1 patients in group 2 had white and red blood cells in the urine on one or more occasions Peripheral edema was observed in 8 cases

in group 1 and in 4 cases in group 2

Age Sex Surface Treatment and Fever

There were no essential differences between the patients in both groups in regard to age sex and surface treatment. The ages varied from I year to 78 years. The sexes were equally divided Dry gauze or petroleum jelly pressure dressings were the most frequent form of surface dressing Four patients in each group were treated with triple dye Four patients in group 1 and 2 in group 2 were treated by the application of tannic acid and silver nitrate. All patients had fever at some time during the course of their illness. There was no significant difference between the two groups as iar as number of patients with fever and intensity of the pyrexia are concerned

### Other Observations

Hypoproleinemia Eleven patients in group 1 and 17 in group 2 had hypoproteinemia at some time during their hospital course almost all the fraction of the plasma protein most lowered was the albumin fraction

Surface area burned In general the patients in group 1 had more extensive burns than did the patients in group 2 In group 1 10 pa tients had 50 per cent or more of the body surface burned while only 3 patients in group 2 had burns of this extent. This marked contrast is also apparent when the extent of deep burn is compared in both groups. Thus, in 12 patients in group 1 the extent of deep burn was 35 per cent or greater of the body surface while in only 4 patients of group 2 was the deep burn of this extent. One patient in group 1 had a conspicuously small burn

Respiratory damage Many patients in each group suffered respiratory damage from in halation of hot air and smoke Very severe grade 4 respiratory damage was sustained by 4 patients in each group

Hemoglobiascum and hemoglobiasura. Hemoglobiaemia was observed in all cases of group 1 in whom the determination was done and issted from 1 to 4 days after the burn. It was observed to a leaser degree in 4 pa tients in group 2 Six patients in this group did not have be moglobinemia. Twelve of the 16 patients in group 1 on whom data are available had hemoglobinuria while only 1 patient in group 2 had hemoglobinura. Hemoglobia casts were seen in the urine of 3 patients in group 7 and in none in group 2 patients in group 7 and 1 none in group 2 patients in group 7 and 1 none in group 2 patients in group 7 and 1 none in group 2

Hemoconcentration During the first 24 hours hemoconcentration was observed in twelve patients in group 1 and in 16 in group 2

Shock Sixteen patients in group 1 and 12 patients in group 2 had clinical shock at some time during the first 36 hours. However the seventy and duration of shock was greater in group 1 than in group 2 Grade 3 shock was observed in 11 cases in group 1 and in only 3 cases in group 2 It should be pointed out, however that 2 patients in group 1 ind no shock and 1 had mild shock

Plasma and serum. The quantity of plasma and serum given was, on the average higher in patients of group 1 than in patients of group 2 the average in group 1 being 29 liters the average in group 2 t.8 liters in the first 48 hours. Most of the plasma was given in the first 14 hours.

Albumis in the form of a 25 per cent solution was given during the first 48 hours to 5 patients in group 1 and to 4 patients in group 2. It was given later to 3 group 1 patients and to 1 group 2 patient.

Mercury The plasma serum and albumin used early in the study contained an organic mercural preservative and some of the patients received enough plasma in relation to their body weight in the first 24 hours to raise the question of mercury toxnoty. However 7 patients in group r received fluids without mercury

Physiological saline in variable quantities was given parenterally to most patients in both groups. The average amount given during the first 48 hours was 19 liters in group 1 and 15 liters in group 2 and 25 liters in group 2.

Parenteral glucose solution 5 or 10 per cent was given to practically all patients in both groups. The average amount given in the first 48 hours was 10 liters in each group

Blood transfusion: Eight patients in group 1 and 10 patients in group 2 received type specific blood transfusions during their course. There was no evidence of a hemolytic transfusion reaction in any patient. Furthermore, there were 10 patients in group 1 who did not receive blood.

Drug therapy. Six patients in group 1 and 18 in group 2 received sulfadruga. This was sulfadiazine in most cases, 3 patients in civing sulfathiazole. Drug levels in the blood were markedly elevated in 1 cases and mod crately elevated in 2 cases in group 1 They were moderately elevated in 4 cases in group 2 group 2.

Sulfadrug crystals in the urine were found repeatedly in 1 case and on 1 occasion in one other case in group 1. They were found re peatedly in 3 cases in group 2. In no instance was this accompanied by agnificant hematurus. There were 7 patients in group 1 who received neither blood transitusions nor sulfonamides, and there were 2 patients who received neither blood transfusions, sulfona

mides nor mercury

Sodium lactate or bicarbonate was given on
entry to 12 patients of group 1 and to 14
patients in group 2:

Districts: Ammophylline, so per cent given cose solution or both were given intravenously to a number of patients in each group. The glucose solution was given in 4 cases and aminophylline in 12 cases, 12 in group 1 and 9 in group 2. In most cases the ambophylline was given for bronchial spasm and not as a diuretic. There was no evidence that the hypertonic glucose solution or the aminophyline had any significant duretic effect in these cases. Albumin was given for possible duretic action to 3 group 1 patients. In 1 of these it seemed to have a definite diuretic action (see Case 4 report) while in the 2 others of effect was observed (see Case 2 report).

Complications and time of death. The most promps of patients were of a pulmonary nature. Pneumonia, bronchopneumonia, and pui monary congestion occurred in about one-ball of the patients in each group. Other complications were atelectasis of the lung in 2 cases pyrogenic plasma reaction in 2 cases, the latter having received grossly contaminated plasma acute hemorrhagic cystitis in 5 cases cerebral edema in 3 cases, and central necrosss of the liver in I case

On the whole the patients in group 1 died earlier than did the patients in group 2 The cause of death was variable. In many cases the injury to the respiratory tract was the chuef cause of death In some death was due to the complications noted above (chiefly pneumonia) but in some cases it was im possible to state what the patient died of more specifically than extensive burns Two pa tients in group 1 died of shock due to burn In only 2 cases could kidney failure be con sidered the chief cause of death

Patients with acute pyelonephritis As was stated before, 2 patients in group 1 are considered separately since although the kidneys in these 2 patients were abnormal morphologically the anatomical lesion was quite different from that observed in the 18 other patients in group 1 The renal lesion in these 2 patients was that of acute pyelonephritis. Both were in shock and had hemo-Patient 16 in globinemia on admission addition had hemoglobinuria Patient 3 had been on constant bladder drainage from the time of admission to death.

Patients in group 2 who died within 6 hours after burn Three patients in group 2 are also considered separately since they differed so much clinically from the remaining patients in this group All 3 had extensive deep burns and respiratory tract injury They were all in profound shock and had marked hemoglobi nemia One was completely anuric while the 2 others excreted a very small quantity of acid urine containing hemoglobin. The non protein nitrogen level in the blood was elevated on admission in 1 patient and normal in 2 patients. All 3 patients died within 6 hours after admission 2 (Cases 21 23) of shock and 1 (Case 22) of asphyriation None showed any renal changes at autopsy

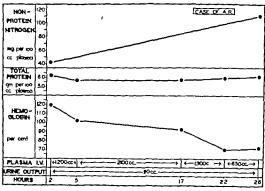

### CASE REPORTS

CARE 20 Extensive deep burns hemoglobinuria shock oligaria atotemia and marked renal changes at

antopyy This 9 year old boy with a noncontributory past history was admitted shortly after receiving deep flame burns of almost his entire body Exam ination revealed a well developed and well nourished boy in moderate distress The total burned area was about 90 per cent Most of the areas appeared to be The skin was hard leathery and brown with very little external coze. Areas were clean The chest was clear throughout The pulse was 100 of good quality blood pressure 110/70 and the

Under morphine sedation 1/13 grain, petrolatum respirations 20. pressure dreasings were applied to all areas except the abdomen which was treated with triple dye By the end of the dressing the patient had received 200 cubic centimeters of plasma containing 20 cubic centi meters of molar lactate He was definitely in shock at this time The pulse was very rapid and thready the feet hands and face (which were the only exposed areas) were cyanotic and cold Plasma was forced in by syringe, 450 cubic centimeters being given in 10 minutes. There was immediate improve ment in the circulation He was catheterized at this time and a small amount of dark brown acid urine was obtained He was left on constant bladder drainage. He was given sodium bicarbonate one half gram by mouth During the next 12 hours the patient received about 2500 to 3000 cubic centi meters more of plasma and 20 cubic centimeters of molar sodium lactate He took only a small amount of water by mouth and vomited as soon as any fluid was taken His pulse varied from 100 to 140 The blood pressure could not be taken because the ex tremities were in dressings. The temperature rose to 104 degrees rectally at 14 hours and exposed areas were sponged with cold alcohol He became stupor ous and the pulse was barely perceptible. Five hundred cubic centumeters of plasma and Sigram of sodlum blearbonate was given rapidly in 10 minutes by syringe with definite improvement in the quality of the pulse Shortly thereafter he began having generalized twitchings and clonic movements each convulsive episode lasting about 5 minutes. Lu minal in 2 grain doses was given intramuscularly The temperature rose to 107 degrees and pulse to 150 and was weak. He remained comatose and died 26 hours after entry He had received a total of 4800 cubic centimeters of plasma intravenously. His total output was 90 cubic centimeters of very dark

Laboratory data The hemoglobin total protein and nonprotein nitrogen data are given in Chart I brown urine There was moderate hemoconcentration on entry which was corrected by the plasma infusions plasma protein concentration remained within normal range The nonprotein nitrogen rose rapidly from a high normal value to over 100 milligrams. Hemoglobinemia was marked Analysis of the first urine specimens revealed a dark brown acid urine specific gravity 1 030 with no acctone, bile or sugar It continued to be dark brown or black. amount of proteinura increased progressively from

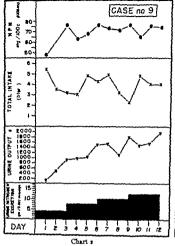

Chart

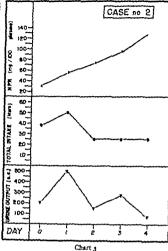

a slight trace to a very heavy trace. The sediment revealed granular casts and y t no red blood cells. The benaldine and bemosiderin stains were positive.

Interry findings B rms covered 90 per cent of the body surface and were chiefly deep. The lungs were congested a d edematons with partial atelectasis of the lower lobes. The combined weight of the kidneys was 160 grams. The cut surface revealed a slightly redder than normal cortex and medulla with minute red streakings converging at the papillae Microscopic examination revealed that the glomer ular spaces contained dark blue granular precipitate. The same precipitate was found in most tubules. There was no modification of the basement membrane of the tufts and no cellular infiltration or endothelial or epithelial hyperplasia. The tubules contained numerous pigment casts. Flity casts were counted in a single low power field (100×) in the medulla. The casts were found in the descending limbs of Henle's loop and collecting tubules. Most of the casts were composed of red granules. Some, however, were brown others blue The particles ranged from fine granules to larger round masses. Most cast particules gave a positive stain (green) for hemorlobin. Mononuclear crils with cosinophilic cytoplasm and pyknotic nuclei were en countered occasionally within the casts. cytoplasm of these cells stained red with hemoglobin stain. The convoluted tubular changes were marked and except for the absence of regenerating epithelium were klentical with that seen in the kidneys of Case 12 There were areas where the nuclei were completely missing and the cells were granular and had filled the tubular lumen with amorphous masses of cytoplasm. There did not appear to be any interatitial edema. There was no leucocytic infiltration. There was no congestion of interatitial vessels.

CARE : Minimal surf ce burn ma ked respiratory trect i jury, no shock totemie and renal chauges at autopry This 43 year old woman received burns at the Cocoanut Grove fire She had inhaled a considerable amount of hot smoke and had lost con sciousness. The past history was not obtained Examination revealed a fairly well developed and well nourshed woman. She was unconscious. She had marked strider dyspnes, and cyanosis. The only external burn was a small area on her nose. The pulse was rapid. During the first 24 hours she received 1000 cubic centimeters of plasma, 1500 cubic centimeters of saline and 1000 cubic centi meters of elucose in water No data are available as to the urine output on the first day. On the second day 500 cubic centimeters of dark urine was passed and on the third day 300 cubic contineters. At the end of a hours because of increasing respiratory distress, a tracheotomy was performed. respirations improved markedly for a brief period. On the third day sulfadiasine was started. The respirations continued to be labored with coarse rales throughout both lung fields. The patient died on the fourth day following a midden increase in respiratory distress.

Laboratory data. On the second day the hemoglobin was 90 per cent and the nonprotein nitrogen

was 94 milligrams per 100 cubic centimeters of plasms. The urine was dark in color with a slight trace of albumin and no sugar or accione. There were 0-2 white blood cells and no casts.

wete or white blood cells and no casts.

Autopry finding: The following were noted a burn dermal, of nose acute laryingo tracheobron chitis (inhalation) congestion of the spicen and liver, bronchopneumonia and edema of the lungs The kidneys together weighed 310 grams. The pale gray plak cut surface of the cortex was clearly demarcated from the deeper stained red-blue pyra mids Microscopic revealed glomerular capsular spaces contained a moderately heavy precipitate. The same precipitate was found also in all tubules Otherwise there was no glomerular change. The capillaries contained blood no thrombi were present There was no modification of the basement mem-There was no endothellal or epithelial cell hyperplasis or inflammatory cell infiltration. The tubules contained casts and showed some damage to the tubular epithelium The casts were found in the tubules of the medulia and less often in tubules of the cortex. The epithelium was so modified in the portions containing casts that it was not always possible to klentify the type of tubule. Collecting tubules and ascending limbs of Henle's loop were recognized in a few instances. The casts were for the most part composed of densely packed fine base-

philic granules There was a brown to red color to some casts. Part of some casts were pale blue and homogenously smooth An occasional cast was composed of larger bright red globular particles. With hemoglobin stains there were many casts of green particles and others of red Recognisable desquamated cells presented red cytoplasm and nyknotic nuclei It should be mentioned that here as in other cases the nonpigment casts stained red and were cell débris la origin. Tubular necrosis was slight and seen most prominently in those portions containing casts. In places only the basement membrane remained elsewhere the epithelium was reduced to very flat cells. The tubular cells gur rounding casts were flattened the cytoplasm deeply cosinophilic and the nuclei pyknotic others had fallen away from the basement membrane seeming to become part of the cast. The convoluted tubules gave the impression of being dilated there being a considerably greater sized lumen than is usual. The cells were low and granular, and many cells con tained no nucles Regenerating epithelium growing beneath degenerated cells was seen only rarely A very rare mitotic figure was found. There was no cel iular infiltration of interstitial tissue and no scars. Capsules, arterioles and pelves were not remarkable.

CASE 9 Extensive deep burn shock hemoglobinurla asotemia transient oligaria impaired urinary

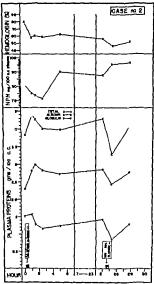

Chart 4

nitrogen excretion and natichanges at utopsy A 19 year old woman with a noncontributory past history received burns over 45 per cent of the body surface, chiefly deep and respiratory tract injury at the Coccanut Grove fire. Initial surface treatment was triple dye following sosp and water cleansing Pulse on entry was weak and rapid. In the first \$4 bours she received is units of plasma, a liters of saline and 116 liters of glucose in water She took Soo cubic centimeters of water by mouth. Her circulation improved over a period of hours and there were no further episodes of peripheral collapse. The urine output was 200 cubic centimeters in the first day and thereafter over a liter dally Sulfadia zine was begun on the third day The free drug level rose to 14 milligrams per 100 cubic centimeters of blood and the total drug level to 18 milligrams per

soo cubic continuctors of blood on the fifth day Thereafter, the sulfadishine was given intermit tently with levels being obtained as given below under laboratory data. On the seventh day the temperature which had been on to soo degrees rose remaining at about roy degrees thereafter. She became markedly dyspreke and there were diffuse musical and crepitant risis throughout the entire chest. Polmonary algus and symptoms increased and the patient expired on the twelfth day

total." Thereafter the drug levels ranged from y a milligrams free" and at on milligrams 'total." The plasma total protein concentration was quarm per soo cubic centimeters of plasma on the farst day with a normal sibumin/globulin ratio. Thereafter the total protein ranged from 4.10 C.1 the normal sibumin/globulin ratio continuing normal. The urine ultrogen exerction rose from a grams daily during the first y days to 10 grams daily from the inith to twelfth day. Urine at the 16th hour dark brown hemoglobin 80 milligrams per 100 cubic centimeters #1.5.1 specific gravity 1010 albumin slight, trace bemoglobin casts hemosabrin, a plus. Thereafter the specific gravity ranged from 1013 to 1017 and the sediment showed an occasional red and white blood cell.

The following were noted Autopsy findings burns covered 45 per cent of the body surface, chiefly deep acute laryngotracheobronchitts (mbronchopneumonia. The kidneys tohalation) gether weighed 310 grams. The cortex was pale and somewhat swollen. Microscopic showed the glomer uli were not remarkable save for vacuolated pink precipitates within the capsular space. The tubules contained casts of the two general varieties and presented evidence of tubular degeneration. The pigment casts were composed of granules varying from brown to red with an occasional smooth, blue homogenous irregular mass. The other casts were composed of cellular débris which was cosmophilic and granular Faint outlines of cells with uclei were present in these casts. There were less casts of this type than there were pigment casts. Casts were not numerous. Usually a maximum of three casts per low power field ( oo X) could be seen Casts were found in the collecting tubules and loops of Henle Desquamated degenerated cells were present within the lumen of the tubules but regenerated epithellum was the predominant feature indicating previous tubule damage. Identification of the tubules involved in this process was often impossible

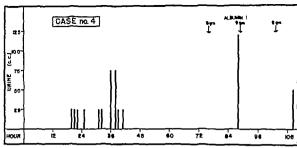

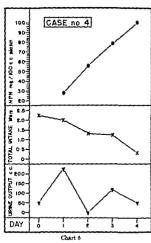

Chart 5

It appeared that the convoluted tubules and possibly ascending limbs of Henle's loop were affected The regenerated epithelium was not as high as was the older epithelium and took a distinctly more basophilic stain Mitotic figures could be seen oc casionally, indicating that the process was still active. The interstitial tissue was very edematous Tubules were widely separated by pale loose stroma and between glomerular capsules and tubules there were widened clear areas. In a few areas newly formed fibroblastic tissue was present in the loose edematous stroma. In more or less discrete patches there was a moderate infiltration with plasma cells and a lesser number of lymphocytes. Only a rare polymorphonuclear leucocyte was found bules were found containing polymorphonuclear leucocytes. It is not possible to say that the inter stitial reaction bore any anatomical relationship to degenerated tubules or tubules with casts. Several large veins contained thrombi partially filling the lumen. These thrombi were composed of fibrin, enmeshed leucocytes, red blood cells and a red granular substance of undetermined nature. In the fargest veins fibroblasts were invading the thrombifrom points of attachment The surrounding inter stitual tissue contained plasma cells and newly formed fibroblasts,

CARE a Extense deep burns shock hemoglo binario astormia oligarno edema and marked vanal changes at audopty. No disarcic effect from 50 per cent glucose or 25 per cent albumin infravenously. This so year old white female with a noncontributory past history received flame burns about 6 hours before entry as a result of an oll stove explosion. She felt fairly well at home and entered because of per sistent pain. Examination revealed a fairly well developed and nourished woman with mixed dermal and deep burns of 30 per cent of her body surface. The blood pressure was 70/40 the pulse rapid and thready. Morphine 1/2 grain was given subcutane county and plasma started intravenously and within oursily and within

the next 2 hours 1000 cubic centimeters of plasma and 800 cubic centimeters of 5 per cent glucose in saline were given intravenously Her blood pressure rose rapidly to 120/80 and her pulse lell to 94 and was of good quality. The burns were then washed and affiver nitrate and tannic acid were applied. In the next 8 hours her blood pressure gradually fell and the pulse rose to 140 and was of poor quality patient was given 1200 cubic centimeters of plasma in a hours with a rese in blood pressure and a fall in the pulse resulting and for the rest of the day her pulse remained about 100 and was of good quality The blood pressure rose steadily reaching a level of 190/110 about 30 hours after entry but in the next 8 hours it had dropped to 130/90 There were no further episodes of hypotension or hypertension. The output was 200 cubic centimeters in the first 24 hours Her hemoglobin fell from a level of 96 per cent on entry to 60 per cent in 48 hours. One thou sand cubic centimeters of blood was given in the next 2 days but the hemoglobin remained about 60 per cent. Small petechiae were evident over the abdomen at 36 hours. The platelet count at this time was 18 000. The petechiae gradually increased until the entire abdomen and chest were covered In the next 36 hours generalized edema became evident. This edema increased during the next day and then gradually disappeared with no evident diuresis or evidence of fluid accumulation in either the thorax or abdomen The patient had been given aminophyllin at 30 hours and again at 40 hours with no apparent divress being obtained output remained low throughout the course and the plasma nonprotein nitrogen rose from 30 milligrams per 100 cubic centimeters plasms on entry to 130 on the fourth day (see Chart 3) Concentrated albumin and 50 per cent glucose were given on the second day and third day without producing any diuresis. From examination of Chart 4 it may be seen that 200 cubic centimeters of 25 per cent albumin intravenously produced a somewhat greater apparent increase in

blood volume as judged by the serial hemoglobin determinations, than 100 cubic centimeters of to per cent glacone. In the farmer instance the plasma protein concentration rose from 3.5 to 4.4, the rise being due to an increase in the albumin fraction, while in the latter case plasma protein fell from 4.5 to 3.5. The temperature had rise no 100 degrees on the second day at which level it remained. The pulse and respirations rose gradually beginning on the fourth day and the patient became urrational and stomorous and eroticed on the fifth day.

suitery satisfic Burns involved 35 per cent of the body surface chickly deep Petcchial hemorhages of the skin I testinal tract myocs dium, recal pelvis and ureter were noted Patient had theumatic heart disease, inactive minimal bilateral hydrothorax 750 cubic continuents pulmonary odema, peripheral edema (feet legs genitalia). The conditioned weight of the kitdneys was 300 grans. On the cut surface and in the pelves were found many minute yellow crystals which could be scraped in diameter). In diameter, in cach kitdney. The pelves therefore marked submoosal kenominate. Along the understhese were many peterbiase. Cortex and medifical were well demarkated.

revealed that the glomerular capsular space con tained a small amount of fine pink granular precioi-The tufts showed no modification of the basement membrane, no cellular proliferation of infiltration, and the capillaries showed no convertion or thromboels The tubules contained moderate numbers of casts. These are most numerous in the medullary regions. A maximum of so not low none field were counted. The casts are composed of appreciates of red to blue fine erapules minuted with which were small amorphous blue mesors and a few desquamated cells (phloring methylene bine). The majority of tubules containing casts could not be majority of tubules containing casts could not be identified but an occasional collecting tubule, ascending and rarely descending limbs of loop of Henle were identified as containing casts. Rarely an intact tubule was found packed with cells. These cells aften appeared to be macrophages containing yellow to red grapules. In other instances there were cells with the appearance of descuemated enthelium. In a instances a few polymorphonuclears surrounded the casts. In Zenker fixed tissue stained for bemoslobin, the larger particles were olive erren in contrast to the red stain taken by descuamated cell débris. Degenerative changes of tubular epithelium was not definitely found except at the sites of casts. However mitotic figures and regenerated epithelium and the finding of desonamated enithelial cells in casts was indicative of tubular damage Many tubules of the medulla contained numerous large vellow particles. The interstitial tissue contains small foci of lymphocytes. Arterioles were not remarkable.

CASE 4 Extensive hurns shock assignia ciena and renal changes at autobry Discretic effect f our 25 per cent album n intrasenously A 2 year old male infant with noncontributory past history entered the bospital as bours after receiving mixed dermal and deep hot water burns of 30 per cent of his body surface. Examination revealed a well developed and nourished anathetic infant. His color was ashen, extremities were cold and clammy pressure was unobtainable polse was rank and thready, rate about 160 and the peripheral veins were collapsed Petrolatum pressure dressings were applied with no preliminary cleansing. On entry plasma was begun intravenously to cubic centimeters being given in 3 minutes following which the patient's color improved the pulse became stronger the rate dropped to 13 and he began moving about The rat of plasma administration was allowed down and in the next so minutes ago cubic centimeters of plasma were given. The patient became pale less active and the pulse was weaker After the rate of administration of plasma was speeded up, the color and the quality of the pulse improved. During the next 5 hours he received 400 cubic centimeters of plasma and soo cubic centimeters of water by mouth, the quality of his puise and his color remaining good. About to hours after injury there was a brief period of peripheral collapse which responded t an increased rate of plasma flow

Shortly thereafter the patient voided for the first time to cubic centimeters of clear light vellow urine He was given 200 cubic centimeters of 5 per cent glucose in water intravenously in the next 2 hours Fifteen hours after the injury the patient had a generalized convulsion. The respirations became rapid and gasping. Cyanosis was marked the pulse very rapid and weak. The temperature was 104 degrees rectally. The patient quieted down in a few minutes but the pulse continued to be rapid and of poor quality. The neurological examination was negative Plasma was begun and after 150 cubic centimeters had run in his color improved and the pulse became slow and stronger. During the next 2 days the patient had a number of similar convulsive seizures despite fairly heavy sedation with sodium luminal. On the third day he had a much more prolonged seizure which lasted about 114 hours. The pulse and respirations became very weak and rapid Coramine and adrenalin were given intravenously with transitory improvement in pulse and respira tions Adrenaun was repeated twice more in the next half hour with the blood pressure rising to 110/80 at which level it remained thereafter. During the first 48 hours the patient received 2250 cubic cents meters of plasma 250 cubic centimeters of 5 per cent glucose in water intravenously 200 cubic centimeters of x per cent glucose in water by clysis and 1500 cubic centimeters of water by mouth. There was some abdominal distention at 15 hours and gastric lavage yielded 150 cubic centimeters of coffee ground material. In the next to hours there was an additional 250 cubic centimeters of similar material vomited The urine output was low during this time the total being 175 cubic centimeters in seven 25 cubic centimeter amounts in the period of 12 to 38 hours. In the next 30 hours the patient received 500 cubic centimeters of blood intravenously 850 cubic centimeters of water by mouth 100 cubic centimeters of 5 per cent glucose in water and 250 cubic centimeters of sodium chloride and sodium lactate solution Ammophyllin and mercupunn were also given intravenously. There was 200 cubic centimeters of vomitus and two liquid gualac negative stools. The patient had started to become no iceably edematous 48 hours after entry and this increased definitely in the next s hours. There had been no urine output for the last 32 hours. At this time 35 cubic centimeters of 25 per cent salt-free albumin was given intravenously (Chart 5). In the next few hours there was a definite reduction of cdema and some beginning bladder duliness which gradually increased. Nine hours later the patient was catheterized and 120 cubic centimeters of urine was obtained. At this time 35 cubic centimeters additional albumin was given. The following morn ing 200 cubic centimeters of 5 per cent glucose in water was given by clysus and 150 cubic centimeters of water was taken by mouth. The edema increased again and following the administration of 35 cubic centimeters more albumin there was some decrease in the edema. Two hundred and fifty cubic cents

meters of whole blood and 31/2 cubic centimeters of aminophyllin were given intravenously and 50 cubic centimeters more urine were obtained During this period the patient was having loose tarry stools. On the fifth day he became comatose and the neck was somewhat stiff Neurological examination was otherwise negative Lumbar puncture revealed clear fluid pressure 300. The patient remained comatose and about 414 days after entry the respira tions gradually increased the pulse became more rapid and weak, and the blood pressure was un obtainable. The respirations became suddenly markedly labored and the respirations and pulse stopped in a period of a few minutes. His nonprotein nitrogen which had been normal on the hist day rose to a level of 100 milligrams per 100 cubic centimeters of plasma shortly before death (Chart 6)

Autopsy findings The following were noted burns as per cent of the body surface mixed dermal and deep acute esophagitis (traumatic-inlying Levine tube) pulmonary edema pleural effusion and abdominal ascites (alight) The combined weight of the kudneys was 70 grams. The cut surface seemed swollen and appeared to bulge slightly. The pyramids were darker than usual Microscopic exami nation revealed the glomerular capillaries con gested the capsular space small and contained pink granular precipitate. There was no modification of the basement membrane or Bowman's capsule. The tubules contained numerous casts and showed extensive deceneration with marked regeneration of the epithelium. A maximum of 48 casts was counted in a single low power field (100X). The medullary region contained the greatest number of casts. The casts were of two main types i.e pigment casts and casts composed of desquamated tubule epithelial debres. The former were most commonly composed of moderately coarse granules of blue or dark green color The individual granules often were of ovold or round form. Less commonly the particles assumed larger rod like green forms. In some casts there were desquamated cellular elements. Pigment casts were found for the most part in collecting tubules or in the ascending portions of the loom of Henle Most of the casts give a positive staining reaction for hemoglobin The casts formed of desquamated necrotic cells were found in the cortex in convoluted tubules and in tubules that could not be identified because of extensive degeneration These casts were composed of brilliantly eosinophilic finely granular material. No nuclear material could be seen. In some instances there were no remaining viable epithelial cells so that the cast was bounded only by the basement membrane of the tubules. In other instances flat basophilic re generating epithelium was seen underlying the eosinophilic masses Mitotic figures were numerous in the regnerating cells. Regenerated cells completely replaced degenerated cells in some instances The tubules did not contain fat droplets of de generation. There was no cellular infiltration or

fibrous of the interstitial therees and no scarring Arterioles and renal pelves were not remarkable

DISCUSSION Observations on renal function and renal changes at autopsy in 47 patients have been described. The patients were separated for purposes of analysis into two groups on the basis of the morphological abnormalities of the kidneys. Group r included 20 patients (Nos. 1 20) in whom the kidneys at autopsy were abnormal. Group 2 included 27 patients whose kidneys were normal morphologically Two patients (Cases 3 and 16) in group 1 were considered separately because the renal lesson found at autopsy was an acute pyclonephritis, entirely different from the renal lesion observed in all other patients of this group In addition 3 patients in group 2 with extensive burns who died very early were considered separately It is possible that in these cases there was not time enough for the appearance of morphological changes that might have been expected from the severity of burn in these patients. These 5 patients are excluded from the following discussion.

The anatomical abnormalities described here in the kidney of 18 patients of group 1 vary in degree of intensity from one patient to the other but are homogeneous in the whole Pigmented casts, epithelial casts, tubular necrosis and tubular regeneration, in cases surviving more than 2 days. The pig ment casts were probably derived from blood pigments. This is indicated by the fact that they were indistinguishable from similar casts found in the kidneys of patients with hemolytic transfusion reactions, and is further confirmed by the presence of a positive staining reaction for hemoglobin in these casts. Furthermore there was a close correlation between the presence of hemoglobinuria during life and the presence of pigment casts

There was a close correlation between the clinical and laboratory findings of renal function and the pathologic observations on the kidneys. All patients in group I had evidence of persistent kidney dysfunction while only 1 patient in group 2 presented such evidence and in this patient it was secondary

to cardiac fallure In the few group 2 patients who had elevated levels of the blood non protein nitrogen, the levels were on the whole much lower than in group 1 patients. In addition the two highest levels recorded in group 2 (Cases 33,38) occurred late in contrast to the early high levels observed in group r There was also a contrast between the 2 groups of patients in respect to urme output. It is well known that during a period of shock of what ever cause there is a marked decrease in the output of urine (18) However in most patients in group I with oligura, this out lasted the period of shock and persisted until death while in all but one group 2 patient the oliguria was limited to the period of shock and in this patient the oliguria was associated with cardiac failure. In those patients of group 1 in whom the oliguria was transient there was evidence of impaired ability to clear nonprotein nitrogen products in the face of a urine output of a liter or more daily

A number of factors can readily be ruled out as responsible for the difference in renal changes in the two groups since these factors occurred with equal frequency in both groups. These are (1) age, (2) sex, (3) surface treat ment, (4) fever (5) plasma protein concentra tion, (6) fluid intake The intake of fluids was somewhat higher on the average in group i than in group 2 This is readily explained by the more extensive burns and higher frequency of shock in group 1 Since the shock in almost all the patients in group I was successfully treated it is probable that sufficient quantities of fluids were given so that their oliguria is not to be explained on the basis of insufficient fluid intake. The types and proportions of fluids given were the same in both groups. (7) Chemotherapy was not a determining factor since 12 patients in group 1 did not receive sulfadruga. In no instance was hemolysis seen as a complication of drug therapy (8) The organic mercurial preserva tive present in some of the plasma, scrum and albumin was not responsible for the production of the renal syndrome since equal numbers of patients in both groups received mercury free fluids and mercury containing fluids. (9) Blood transfusion. The possibility that the renal lesion was produced by hemolytic transfusion reactions can be ruled out since there were 8 patients in group 1 who did not receive blood at any time during their course, and in the remainder there was no evidence of a hemolytic reaction

The 2 groups of patients differed mainly in respect to the following factors (10) extent of burn and especially extent of deep burn (11) occurrence severity and duration of shock and (12) presence of hemoglobinuma.

Extent of burn The chief complications of burns such as toxemia progressive anemia and nutritional disorders are directly related to the extent of burn and particularly the extent of deep burn This holds true in regard to renal complications, since two-thirds of the patients with kidney dysfunction had deep burns of greater than 35 per cent body surface while only one-sixth of the patients without kidney dysfunction had burns of this severity One patient (Case 1) in group 1 had a very small surface burn but had very extensive respiratory tract damage. There were 3 other patients in group 1 and 4 in group 2 who also had severe respiratory tract damage. The problem of respiratory tract injury as a complication of thermal burns has been discussed elsewhere by Finland Davidson and Levenson

Shock As would be expected from the fact that the patients in group 1 were the most severely burned the occurrence of shock in this group of patients was more common and more severe and prolonged than in the patients in group 2 This difference is important since shock per se is known to have a profound effect on kidney function. The occurrence of oliguria during shock is well recognized and is presumably due to a markedly decreased blood flow through the kidney (18) The blood flow through the kidney may be reduced to as low as 5 per cent of its normal value during shock at a time when the general blood flow is only reduced to 50 per cent (18) That the renal failure observed in shock as sociated with burns may be different from that seen in other types of shock is suggested by the experiments of Olson and associates on dogs. They showed that in burn shock restoration of the blood pressure by infusions of saline did not increase the output of urine

while such infusions did increase the urinary output in hemorrhagic and tourniquet shock The effect of shock on renal function is related to the severity and duration of the shock Disturbances in renal function are more severe and more protracted when the shock is profound and lasting Irreversibility of the function and morphologic alterations of the kidneys following severe shock have been described by Van Slyke He showed that severe reduction in the renal blood flow during circulatory failure for a period of hours follow ing hemorrhage is often followed by markedly impaired kidney function and pathologic changes in the kidneys consisting chiefly in tubular necrosis and the presence of pigment casts in the tubules.

Hemolysis The third factor of apparent importance in the pathogenesis of the renal injury following burns is intravascular hemolysis, since renal injury has been observed in a number of other conditions in which intra vascular hemolysis occurs (2.7 21 28.32) In travascular hemolysis occurs in all severely burned patients and is apparently caused by a direct action of heat on the red cells of the blood circulating in the burned areas (23) Its occurrence and severity are directly related to the extent of deep burn and, as would be expected hemoglobinemia was greater in the patients in group I than in group 2 Hemoglobinuma was seen in nearly all the group I patients and in only I pa tient in group 2

Monke and Yuile in dogs and Altschule in men have demonstrated that hemoglobin is excreted in the urine only when the levels of free hemoglobin in the plasma reach values of about 150 milligrams per 100 cubic centimeters of plasma. Below this concentration it is apparently completely reabsorbed from the glomerular filtrate by the renal tubules. In chronic hemoglobinemia in dogs the threshold is lower which has been explained by a supposed saturation of the tubules with pigment derived from red cells (12) When hemoglobinemia is associated with shock the conditions for the appearance of hemoglobi nuria may be different. Absence of hemoglobinuria in the presence of a marked hemoglobinemia in such cases could be due to

the decreased glomerular filtration caused by the vascular hypotension and the decreased renal blood flow. Furthermore if anuris of whatever cause is present as was the case in one of our patients, and as has been reported by DeGowin it is obvious that no hemoglobinum can occur even in the presence of marked hemoglobinemis.

If the renal damage is a direct toxic effect of the products of intravascular honolysis it can be producted only if the products of red cell hemolysis reach the kidney tubules. This seems likely since in these cases hemoglobinuma and not merely hemoglobinemia is associated with renal leasons. On the other hand, it may be just a question of degree of hemoglobinemia, since hemoglobinemia was more marked in the patients with hemoglobinuma than in those without hemoglobinuma than in those without hemoglobinuma.

Renal injury sometimes of a severe nature is sometimes seen following hemolytic blood transfusion reactions. The renal syndrome of hemolytic transfusion reactions includes oli guria or anuria, azotemia and often uremia Morphologically the kidney changes such as pigmented casts in the tubules and tubular necrosis are strikingly similar to those seen in patients with severe burns. Here also as in the kidneys of burn patients, there is no apparent correlation between the number of casts and the extent of tubular necrosis (7) Other types of intravascular hemolysis have also been shown to affect the kidneys in a similar fashion. Renal failure has been de scribed in cases of paroxysmal nocturnal hemoglobinuria (21) hemoglobinuria due to quinine pousoning (28) black water fever (11) acute hemolytic anemia due to sulfonamides (12) and hemoglobinuria of obscure origin (2)

The mechanical obstruction which may be caused by the purment casts in the tubules seems quantitatively inadequate to explain the renal failure. It is possible that the tubular necrosis may play a part although the extent of tubular necrosis again does not seem sufficient to account for the failure. The sections of the kidney provide no information on the function of the glomeruli which may be impaired although their structure appears

normal. The identity of the substance or substances in hemolyzed blood which are responsible for the kidney injury and the mechanism of action are still debated. In dogs reduced hemoglobin and exphemoglobin do not appear to be toxic, while methemoglobin appears to be toxic in the presence of an acid urine. If the urine is alkaline methemoglobin is also nontoxic (4) It has been shown that when intravascular hemolysis occurs, part of the hemoglobin is oxidized to methe The application of these moglobin (27) observations to the cases studied here is obvious when one remembers that methemoglobin has been found in the blood and urme of burned patients (23 24) and that the initial urines of most burned patients are acid. It is also possible that the products of he molysis are particularly 'toxic kidneys of patients in shock. Under the tonditions of relative ischemia and anoxia, the kidney may be more susceptible to injury I uile and his associates have shown recently in experimental animals that renal injury by bemoglobin occurred only when the Lidney had been damaged previously. Another possibility is that some other constituent of the red blood cells set free during hemolysis, for instance the stroma, is toxic since solutions of hemoglobin are much less toxic than is hemo-

lyzed blood (13) The problem of the toxicity of hemolyzed blood is intimately linked with the question whether alkalinization of the urine is in any way preventative of renal damage question in relation to the kidney dysfunction in patients with burns cannot be solved on chnical grounds alone since practically all severely burned patients have an acid urme when they are admitted to the hospital and intravascular hemolysis has already existed for at least an hour before alkalinusation of the urine is attempted. No studies in animals comparable to those of Baker and Dodds on the effect of alkalinization on the renal dam age following hemolytic blood transfusion reaction have been made. The effect of alkalinusation of the urine after hemolysis has been present cannot be evaluated from the data reported here since despite the adminitration of alkali on entry the urines remained

acid during the first 12 hours in most patients Walker reported no benefit from early alka linization in his patients with burns

The renal syndrome of severe burns is similar to the renal syndrome associated with erush injuries. The urine in the latter syn drome, however contains myoglobin rather than hemoglobin and the pigmented tubular casts have also been shown to contain myoglobin (5) It is believed that the myoglobin originates from the crushed muscles. Idiopathic paralytic myoglobinuria which is rarely encountered in man but is occasionally seen in horses is also characterized by myoglobinemia and myoglobinuria and a clinical and pathologic renal picture entirely similar to that found after crush injury. Shen and Ham and Taylor and associates (24) have looked for myoglobin in the blood and urme of some burned patients but in no case was any found Kidney dysfunction and renal changes similar to those described here have also been reported following severe traumatic injuries (noncrush) with shock

The azotemia observed in this series of patients deserves special comment since it may be due in part, to an increased production of nonprotein nitrogen in the presence of a failing kidney. The very rapid rise in non protein nitrogen values observed is best explained by a factor of increased production together with decreased excretion. This view is further supported by the fact that there is an increased breakdown of proteins in burns (25).

Fartition studies of the nonprotein nitrogen products in the blood and urine of some of these patients with azotemia have revealed an increase in the residual nitrogen fraction (25,30). This has not been found in all patients with clinical and pathologic changes. Its significance is not known at present

There is no evidence in the present series of cases that ammophyllin or hypertonic glucose solution intravenously led to any diuresis in the patients with impaired renal function. In a case following the administration of albumin intravenously there was an increase in urine output. In 2 other patients to whom albumin was given for a possible diuretic effect, there was no increase in urine output.

It would appear that a very important measure to be taken for preventing renal damage is the prompt and vigorous prophy laxis and treatment of shock. The efficacy of early alkalinization has not been definitely evaluated The injection of reducing agents to reduce the methemoglobin appears logical but has had no adequate clinical or experi mental trial. Once repail dysfunction has appeared care must be taken in the administration of fluids particularly sodium-contain ing fluids, to avoid overloading the circulation Ammophyllin and hypertonic glucose have not proved useful diuretic agents and the latter in the presence of hypoproteinemia may lead to dangerously low plasma protein concentration Albumin should be tried. particularly if there is hypoalbuminemia and peripheral edema. A possible danger would be the production of pulmonary edema. The use of diathermy (10) x ray (20), decapsulation (1), sympathectomy (20) and spinal anes thesia (20) have not been evaluated

It should be mentioned that most of the patients with renal dysfunction died of causes other than renal failure. However it is possible that if these complications can be avoided the patient would go on to death from renal failure. In such cases it would be useful if measures could be taken to tide the patient over until renal tissue has had an opportunity to regenerate and, possibly function to be restored Extravascular (26) or peritoneal dialyzation (22) might be useful if they can be carried out practically and successfully

SUMMARY

1 Forty-seven patients with burns were studied in an attempt to establish a correla tion between kidney function during life and morphologic kidney abnormalities at autopsy

2 Twenty patients had abnormal kidneys at autopsy and except in 2 cases which showed pyelonephritis the renal lesions consisted of tubular necrosis and the presence of pigment and cellular casts in the tubules. The remain ing 27 patients had no significant renal morphologic changes

3 The pigment casts gave positive "hemoglobin stains" but no more specific identification was made

## A NEW METHOD OF TREATMENT FOR SEVERE FRACTURES OF THE OS CALCIS

### A Preliminary Report

KENNETH H PRIDIE, F.R.C.S., Briatol England

In the past a fracture of the os calcis was a relatively rare injury confined very largely to window cleaners. Modern warfare however with the introduction of the torpedo land mine paratroop landings, and other features of warfare has increased not only its absolute incidence but also the relative frequency of the severe highly comminuted type. Despite the most energetic treatment the resultant disability remains a serious one. Patients are left with persistent pain stiffness inability to walk over rough ground or do ladder work or indeed any form of hard manual labor.

In those cases in which the subastragaloid joint has not been affected early movements

. I rom the Fracture and Orthopaeriic Departments of the Bristol Royal Hospital  $\,$ 

lig 1 Recon truction of the upper surface of a ladir

fractured or calcu-

and freedom from weightbearing for 6 weeks produce good results, and the patients are able to return to their preaccident occupations. But in others even when the fracture does not appear to be a serious one subastrated galoid arthritist develops out of all proportion to the x-ray findings so that the end result is much worse than would be expected the disability consisting as before, of pain and stiff ness. Despite individual variations in toler ance to pain the findings in a large number of patients are remarkably consistent.

Several views of a fractured os calcis were taken and from these the upper surface of the os calcis has been reconstructed as shown in Figure 1. The disruption and distortion of the subastragaloid joint can be seen. Any form of treatment to correct and get hair alignment of this complex joint surface is obviously impossible. Consequently, the patient develops a severe subastragaloid arthritis.

The lateral view which is illustrated in Figure 2 shows how the os cales has been broken on the wedgeshaped lower border of the astragalus

Fig. 2. Lateral view showing os calcis broken on wedgeshaped lower border of astragalus.

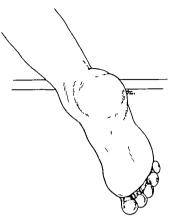

Fig. 5. Condition of foot at operation grossly edeniatous over heel

tient lynng prone an incision 5 inches long was made in the midline from 1 inch above the back of the os calcis over the point of the heel to the anterior end of the bone In desecting the two flaps care was taken not to separate the skin from the deep structures in order to preserve its blood supply. The plantar fascia was spit longitudinally. The os calcis was saved in two slong its long axis and shelled out so as to leave intact the penosteum and the fibers of the Achilles tendon which pass over the bone to become continuous with the plantar fascia.

Fig. 7, left. Exposure of os calcis. A Cut edge of plantar fascia

Fig. 8. Os calcis completely removed. Astragalus exposed. A astragalus B tendon permeus longus C flexor hallucus longus D, flexor digitorum longus, E, soggy edematous tissue in foint, seen after removal of os calcis.

Fig. 6 Incision. Foot in sterile stockinette.

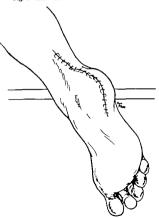

Fig 9. Suture of wound. Incision closed. Restoration of normal outline.

The cortex of the os calcis was extremely thin and the fragments spike like, resembling a broken glass bottle. Figure 4 shows the fragments removed at an

operation for excession of the os calcis

The under surface of the astragalus could be easily seen and was not fractured. It was noted that there was great swelling and bruising of the soft tissues and it is undoubtedly the tension in them which leads to the fibrosis which causes so much stiffening of the joints and the small muscles. The operation not only removes the damaged bone and joint surface, but also relieves the soft tissue tension and reduces the general rigidity of the foot. The wound was closed by suturing the insertion of the schilles tendon, now freed from bone, to the plantar fascia. The two halves f the perioateum and the skin and fascia were sutured in layers with cotton. Two gause pads were placed on each side of the beel to maintain its natural shape and the usual dressings and a firm bandage were applied. The foot was then immobilised in plantar flexion with plaster of Paris.

When the plaster was removed 10 days later the wound was soundly healed and active movements were commenced. Two months after the operation the patient started walking, and was discharged after a months. A year later she walked well and was able to dance. At 18 months she walked without a limp had no complaints, and stated that she was abl t do anything. She could stard on tip-toe and when walking it was impossible to tell which foot had been injured. There was no loss of power and she had full range of inversion and evenion, and freely mobile meditural and too joints. In appearance the

foot was perfectly normal

Local Section 10 Get aged 50 years fell adulation of lofeton a concrete floor no December 21 your and sustained a communited fracture of the left or calcie. It was operated to the next day and almost the whole or calcis was removed except the antenor unt. He was able to posta to work after 6 months and ha been at work ever since. He wasks normally and a salte to run. He can stand on tip-toe and the re is no mable tack of power in the left teg. The Arbillot tendon appears to be as strong in the left side a the right. The appearance of the foot is good and all movement are excellent.

#### AFTER TREATMENT

The for t is immobilized in the original plaster for 1 month. The position of plantar flexion is to ensure relaxation of the Achilles tendon so that its new attachment is not strained. At the end of 4 weeks the sutures are removed and active nonweight bearing exer uses are commenced. The important exer tises are inversion eversion and circumduction. Posttraumatic edema is prevented by in isting that the leg be not allowed to hang down during the 2 weeks immediately follow.

ing removal of the cast except during periods of exercise

When the patient feels able to walk be is encouraged to do so. The average period is about 6 weeks. It is important to see that be is taught to walk correctly and without a lump

#### RESULTS

This new method of treatment of fractures of the os calcis has been performed 15 times to date and the 2 cases reported were the first and therefore have been observed over a considerable time. Three years have now elapsed since the first operation was performed and this girl has an excellent result with practically no disability. The second patient, a bricklayer has now been working for 2 years, without disability.

Two cases were not satisfactors. One a man aged 63 fell 14 feet from a plank directly on to his left heel with the knee straight. He sustained a very severely comminuted fracture of the left os calcus and the os calcis was removed. He made a very poor recovery and got causalgic pains in his leg and at a later date the leg had to be amputated. The section of the foot afterward showed that there was a condition of arteriosclerosis present and be had very poor circulation. There was arthritis in all joints of the foot which was completely stiff and rigid. Whatever treatment this man had he would have had a poor result. Another patient for whom the os calcis of both feet was removed was an old man who had fallen 20 feet and landed on his heels. He also had a very poor result. These were the only two really bad results out of the 15 cases I have done and all the rest of the patients are doing exceptionally well

#### COYCLUSIONS

The results of this operation have been so gratifying that this preliminary report is published in order that others may try it. It probably should be reserved for the several comminuted fractures and like other existence of the strong legation of bones in the foot it is a somewhat difficult operation because of the strong legaments attached to the bone. Unless one is careful to avoid a postoperative hematoma there is risk of sepsis. The operation should

be performed as soon as possible after the in jury in order to prevent intrafascial tension from bleeding and edema which causes ischemia and subsequent congealing of the intrinsic muscles and leads to stiff midtarsal joints and stiff toes. Careful attention must be paid to the after treatment. The chief advantages of this method are

- 1 Freedom from pain
- 2 Good range of inversion and eversion
- 3 Mobility of the whole foot
- 4 Good toe action
- 5 This operation will undoubtedly save many an injured foot from amputation

# LARGE RETROPERITONEAL METASTASIS FROM A SO CALLED CARCINOID OF THE SMALL INTESTINE

JAMES A DICKSON M.D. EDITH M. PARKHILL, M.D. and PAUL C. KIERNAN M.D., Rochester Minnesota

ARCINOMAS of the small intestine are comparatively rare comprising about 3 per cent of all intestinal cancers. The so called carcinoid tu mors constitute approximately a fourth of all malignant neoplasms of the small bowel. These tumors have also been termed argen taffinomas chromaffinomas paragangliomas and primary carcinomas. They occur at least two times more frequently in the appendix than in the small bowel However this type of neoplasm has been known to occur in all locations of the gastrointestinal tract from cardia to anus. In the small intestine carci noid tumors are characterized particularly by occurring in older persons and by the multipli city of their primary lesions in contrast to the single primary lesions occurring in the appendix, which are seen most frequently in younger persons. The present report is concerned with a single small primary growth in the ileum with extension into the mesentery and a large retroperitoneal metastasis of both surgical and pathologic interest.

#### HISTORICAL ASPECTS

Credit is due to Lubarsch who in 1888 clearly distinguished these neoplasms from ordinary adenocarcinomas occurring in the gastrointestinal tract. He reported 2 cases of multiple nodules in the ileum and designated From the Division of Surgray Mays Foosdation, and from the Section on Surgray Mays Foosdation and Surgray Mays Foosdation a

the lesions as primary carcinomas although they appeared somewhat atypical. Ransom in 1890 described i case resembling that of Lubarsch in which the neoplasm had spread into the mesentery and metastasized to the liver

It was Oberndorfer who in 1907 termed

these neoplasms carcinoids to express their malignant appearance in contrast to their benum clinical course. Based on a study of 6 cases of multiple tumors of the small bowel Oberndorfer's description of these neoplasms in summary is worth quoting in part in Forbus translation because some of the points may ment criticism in light of the behavior and character of lesions as reported since that I The tumors are usually multiple 2 The cells are largely undifferentiated masses. but may show glandular form 3 They are circumscribed and have no tendency to infil trate the surrounding tissue. 4 Growth is slow no large size being obtained. 5 The tumors are of a harmless character 6 They he regularly in the submucosa with frequent projections into the mucosa. 7 The stroma is smooth muscle derived from muscularis. We shall not comment in detail on the foregoing points of Oberndorfer's description suffice it to say that carcinoids certainly are not to be regarded as benign and harmless, especially when located in the small bowel

In contrast to the conception of Oberndorfer and in support of Bunting Burckhardt con-

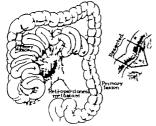

Fig Relation of small bowel t the retroperitoneal mass.

sidered these neoplasms definitely of basal cell character and analogous to the basal cell can cers of knompecher. While meroscopically resembling basal cell epitheliomas superficially these tumors, unlike basal cell cancers, will definitely metastasize as is indicated in reports published within recent years.

#### ORIGIN OF THE SO CALLED CARCINOID TUMORS

The exact cell or cells of origin of these tumors have not been conclusively demonstrated and authorities are not agreed. The weight of the evidence seems to be in favor of their origin from the argentaffin cells found distributed irregularly in the gastrointestinal tract and notably within the crypts of Lieber kuchn The three types of granular cells located in the intestinal tract and described by Schmidt Kultschitzky and Paneth all seem to be implicated as possible sources of these neoplasms. It was Gosset and Masson (7 11) who first showed that certain cells situated at the bases of the crypts of Lieberkuehn reduce an ammoniacal solution of silver salts. The granules in these cells are stained by the chromaflin and silver impregnation methods and by various other stains, perhaps depending on their different functional stages. No explanation of the histogenesis of carcinoid tumors of the small intestine can be accepted without some degree of reservation (1) There may be a common cell of origin or any of the three types mentioned earlier in this para graph and described in detail by Kull may be their source under various attrations

PATHOLOGIC ASPECTS OF SO CALLED CARCINOMY
TUMORS OF THE SMALL BOWE

As mentioned previously these lesions occurring in the small intestine are frequently multiple and occur in an older age group that those found in the appendix, which are unally single (17) The primary tumors are characteristically small in contrast to the much larger metastatic foci. They are char acteristically yellow and frequently one may suspect the diagnosis grossly after sectioning the lesions. Most frequently the lesions do extend into the mucosa and lumen of the bowel but this is not always so in some cases the lesions seem to extend outward into the muscular coats with little or no projection into the lumen Their growth in the intestinal wall results in kinking or angulation of the involved segments. Gross ulceration of mucosa may be absent a fact that explains the absence of intestinal bleeding in many of these cases.

Microscopically these tumors consist of cuboidal, spherical, or cylindrical cells at ranged in small irregularly shaped groups or masses. The nuclei are vericular and rounded or ovoid. The cell groups or nests are usually predominantly solid. The lesions are usually seen in the muscularis mucosae and extend into the mucosa and muscular coats of the intestinal wall. The cytoplasm of these cells has usually an industriet border and is finely granular These granules are both chromaffin and argentaffin The cells on the outermost border of the masses or groups frequently may be seen to be arranged in parallel fashion and assume a cubical shape recalling a similar pat tern seen in basal cell cancera. This feature is more prominent in the fresh frozen sections than in the fixed paraffin sections showing the tumor cells. The cytoplasm of the tumor cells may be finely vacuolated because of the presence of the lipoid material to which the yellow color of the tumor is due. The relative uniformity of pattern of these groups or masses of cells the lack of hyperchromatism the regularity of their nuclei and partial opacity seem to indicate low malignancy Close examina-

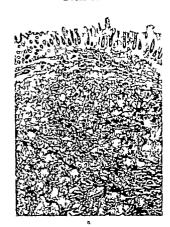

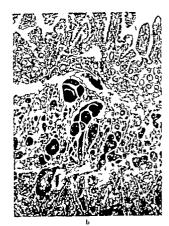

Fig z a, Primary lesion showing tumor cells in and be neath the mucosa of the ileum (hematoxylin and cosin, ×27)

tion of the histopathologic features of these neoplasms of the small bowel does not seem of value in distinguishing those which have metastasized from those which have not metastasized and the picture seems to be similar in the two instances

These neoplasms are carcinomas and are characterized by slow growth Burckhardt remarked that Metastass from carcinoids is merely a matter of time. The malignancy of those in the small intestine is manifested much more frequently than the malignancy of those occurring in the appendix Dockerty Ash burn and Waugh (4 5) noted metastasis in at least a third of their cases in which the neoplasm occurred in the fleum.

The carcinoid type of carcinoma spreads by the lymphatics and by venous invasion by the tumor cells. The likeness of these neoplasms to basal cell epitheliomas here terminates because the latter do not metastasize per meate lymphatics, or invade veins

The term carcinoid may be a good term only so far as it distinguishes these neoplasms from other ordinary adenocarcinomas of the

 Argentaffin tumor cells arising in mucosa of small bowel (Masson silver impregnation method, ×27)

intestinal tract. However it should be emphasized again that these tumors are not harmless or benign but malignant and that they will infiltrate and metastasize and may eventually result in the death of the patient Some reports of cases in recent years have even indicated disseminated metastasis as in the case reported by Watz. Even with metastasis in the liver and other widespread regions it should also be emphasized that provided the primary tumors are removed the patient may live for many years in good health as may be anticipated from the very slow growth of some of these tumors. In spite of their slow growth and mild clinical manifestations in many cases, we consider these neoplasms carcinomas.

#### CLINICAL ASPECTS

Symptoms, when present are usually those of a chronic intestinal obstruction resulting from kinking of the involved segments of the bowel. Intussusception of the bowel may occur. Bleeding into the intestinal tract is most frequently absent. The patient is usually not very ill and most often loss of weight

 $\Gamma$  g. 3. a, Permeu al collection of tumor cells from mesenteric metastatic focus (hematoxylin and coda,  $\times$ 180)

b, \ot deeply stained endothelial cells lining periorand space (Schmori's method for chromafia cells, X 80).

is not pronounced. In some of these cases the neoplasms are reported as being silent but in the small bowel they frequently give symptoms of obstruction Occasionally there may be a palpable abdominal tumor

Roentgenographically, one may be able to demonstrate slight kinking and angulations of the involved portions of intestine associated with a small tumor projecting into the intes tinal lumen The Linking and the tumor may

### be the only signs demonstrable SURGICAL ASPECTS

The ideal surgical management for carcinomas of the carcinoid type involving the small bowel is resection of the segments of bowel containing the small single or multiple primary lesions with removal of all metastatic foci when feasible, including the involved lymph nodes. It is only in very rare instances because of the size and strategic location of metastatic masses, that it may be inadvisable to attempt their complete removal However when removal of the primary lesions has been performed even with metastatic involvement, the prognosis may be good because of the slow growth of these neoplasms. When patients with metastatic foci located retroperitoneally in the liver or in other locations have had the segments of small bowel containing the pri mary tumors resected, followed by anastomosis of the remaining segments of bowel they have been known to live for many years.

It is important not to overlook multiple small primary lesions throughout the extent of the small bowel or even in the large bowel in these cases at the time of operation primary lesions may be very small and diffi cult to palpate but their presence may be manifested grossly by a slight kinking or angu lation of the involved segment or segments of

It is not possible to state whether removal the bowel of the primary tumor may have a beneficial effect on the metastatic foci from neoplasms of this type. Because of their slow growth metastatic tumors may be present for a long time without revealing their presence.

In summary the ideal form of surgical management seems to be as radical a removal of the primary lesions and any metastatic foci

as is feasible. When resectability is limited to removal of the primary tumor or tumors, the prognosis may be good and the patient may live for many years in health sufficiently satisfactory to carry on all normal activities in spite of even large metastatic foci

### REPORT OF CASE

The patient a former nurse was a woman 65 years of age who appeared in fair general health She was first seen at the Mayo Clinic July 16 1945 when she stated that she had been fairly well until 5 years ago at which time she became constiputed and began to take dally laxatives At no time had she noticed any bleeding from the gastrointestinal tract A senes of roentgenographic studies had been done and at this early period her condition was diagnosed Two years ago she noticed no improvement and had a second series of roentgenoas spastic colon. grams taken At this time she was told that there was nothing abnormal to be found in her intestinal tract. She had complained for the past year of pain in the right upper quadrant of her abdomen which had been relieved for short periods by colonic irriga tions She had not noted any bleeding or tarry stools There had been no nausea or vomiting There had been no saundice or colle of any kind within recent years Systemic review revealed a history of low back pain during the past year which she had noted most severely during change in position Appendec tomy had been performed 15 years ago and left mastectomy for a benign tumor 12 years ago Ovar iancystectomy had been performed a years previously

Physical examination. The systolic blood pressure was 140 millimeters of mercury and the diastolic pressure 83 the pulse 80 and the temperature 93.6 degrees F The important physical findings were largely limited to the abdominal examination. There was a rather large cylindric, firm alightly tender mass located in the midabdomen, extending longi tudinally to the right of the midline and measuring approximately 10 centimeters in length and 6 centi meters in width The mass was medial to the usual position of the cecum and was only slightly movable No other masses were palpable

Clinical studies were then made. The excretory urogram was essentially negative on each side Studies of the colon also gave negative results and a simple rocatigenogram showed only an opaque real due in the colon. The abdominal field was otherwise negative roentgenographically Complete studies of the blood and urinalysis revealed normal findings.

Operative procedure (abstracted in part) Operation, commisting of resection of a portion of the Beum Beolleostomy (side-to-side) and removal of a specimen from the retroperitoneal tumor for diagnosis was performed by one of us (P C. K.) on August 7 1945 The operative diagnosis was retroperitoneal mails nant tumor with involvement of the mesentery of the small bowel and primary lesion in the small bowel.

Examination of the stomach, colon and first por tion of the duodenum gave negative results. The gall bladder was distended and thin walled but con tained no stones. The liver and pancress were not mal On examination of the pelvis, it was observed that the uterus was atrophic and the adnexa were negative to palpation. The small bowel was normal throughout the jejunum and upper part of the fleum but about the middleum the mesentery was much shortened and was attached to a retroperitoneal mass. There was a slight kinking or angulation in this portion of the ileum and a small nodule could be seen extending to the seroul aurisce. At this same segment of the lieum approximately 3 feet (or em ) of the lower portion of the fleum was closely adherent to this mass. The tumor although not completely fixed, involved the entire root of the mesentery of the small bowel and was closely adherent to the large vessels. Figure 1 illustrates diagrammatically the relative position of the retroperitoneal mass and its relationship to the small bowel. It was thought best not to attempt removal of the retroperitoneal mass. Approximately 3 feet (01 cm.) of the lower part of the fleum was resected including the involved in durated portion of the mesentery the ends of the bowel were turned in and a side to-side anastomosis was performed. The anastomosis was about 3 to 4 feet (or to 122 cm.) proximal to the fleocecal val e and seemed satisfactory. The appendix had been removed previously elsewhere. Biopsy of two specimens from the retroperitorcal mass was performed for diagnosis

Pathelegic aspects The resected portion of the fleum contained a small rounded nodule measuring 1.4 by 1 centimeter located within the wall of the ileum and extending to the serous surface and also several irregular nodules located within the mesen tery of the Geum just beneath the primary lesion. The cut surface of the primary lesion wa smooth and vellow and the lesion appeared to involve predom inantly the submucosa and muscularis but dal not project into the lumen of the small boxel. The involved mesentery wa firm and irregularly shaped and appeared more whitish than the yellow primary lesion. The two small pieces of tissue from the retroperitoneal mass presented an occasional yellowish spot within their substance Microscopically see tions from the primary lesion from the involved mesentery and from the retroperitonesi mass were all similar and characteristic of those of carcinoma of the carcinoid type. The tumor cells were all microscopically identical in each location. The tumot cells were arranged in solid groups or masses made up predominantly of spherical cells. The cytoplasm was finely granular with industriect cytoplasmic borders and the muckel were small rounded or ovoid and vesicular. The fine granules within the cytoplasm of all these tumor cells in each location were both argentaffin and chromaffin. Figure a shows one of the sections taken from the small primary lesion within the wall of the ileum. Figure 3 illustrates one of the sections taken from the involved mesentery of

the fleum. Figure a is representative of one of the sections taken from the retroperitoneal mass, it is evident that the small levion in the wall of the fleum was the primary site and that the nodules in the meantery and the large retroperitoneal mass, which greatly exceeded the volume of the small primary lesion, were metastatic foot. All of these locations, including the primary lesion in the illeum showed carrelmons of the carricold free

Pest prist ere are. The postoperative course was uneventful and the patient was dismissed from the hospital August 14, 1915 and from the clinic August 24, 1915 in a satisfactory condition.

#### COMMENT

Some of the important surgical and pathologic aspects of carcinomas of the carcinold type involving the small bowel have been previously discussed

The case herein reported of a so called carcinoid presented several unusual features of both surgical and pathologic interest. It was illustrative in many respects of these tumors occurring in this portion of the small bowel except that in this case there was only a single primary lesion. However, the rather extensive involvement of the mesentery and the large retroperitoneal metastasis were unusual features. The most unusual feature of this case was the strategic location of the large retroperitoneal mass at the root of the small intestine in proximity to the great vessels in such a manner so as to make its removal inadvisable to attempt In spite of the fact that it was not possible to remove the large retroperitoreal mass, it was possible to remove the primary lesion and the involved mesenters and thus avert any future threat of obstruction which indeed is one of the most likely complications with neoplasms of this type involving the small bowel.

#### SUMMARY

A case of so called carcanold of the Bern with a large retroperitoneal metastasis has been presented. The strategy location of the large retroperationeal mass at the root of the mesentery of the small bowel prevented any attempt at excision but it was possible to remove the primary lesion in the fleam with the involved mesentery and thus relieve any further possibility of obstruction. The case presented illustrates well the fact that there neoplasms can no longer be regarded as benign

and harmless We consider these so called carcinoids of the small bowel to be grade i (Broders method) carcinomas of the carcinoid type in order to distinguish them from the ordinary adenocarcinomas of the intestinal tract. Designation of these neoplasms as grade r carcanomas indicates their slow growth and low malignancy It is felt that the histopathologic picture of those neoplasms which have metastasized is similar to the picture of those which have not metastasized Therefore one is unable to predict on the histopathologic basis which of these neoplasms will metastasize

## INTRATHORACIC TUMORS OF THE SYMPATHETIC NERVOUS SYSTEM

#### R. L. HOLLINGSWORTH, M.D. FA.C.S., Washington, D.C.

FEOPLASMS of the sympathetic nervous system are widely dis tributed, having been reported as occurring in the adrenal (most frequent site) abdominal cervical, thoracic, and pelvic sympathetics the jejunum, celiac ganglion, mesentery liver coccygeal body uterus, cavity of the nose skin and subcutaneous tissue, scapula region and carotid body Their occurrence within the thorax while not rare, is still unusual enough to war rant their being classified as a curiosity by Gray and to justify the continued reporting of individual cases or small groups of cases. More often than not, they are symptomless their discovery being quite accidental. For this reason an accurate estimate of their in cidence can not be made. Mass chest x ray surveys such as preinduction pre-employ ment, and school examinations will inevitably lead to the more frequent discovery of intrathoracic neoplasms, and their removal and consequent correct diagnosis will follow

The present communication deals with the occurrence of these neoplasms, the embry ology of the sympathetic nervous system in its relation to their formation, a discussion of their characteristics and a detailed report of 7 cases which have occurred at the University of Michigan Hospital. In addition the author has found 63 cases of intrathoracic sympathetic tumors reported in the literature Of these 43 or 68 2 per cent were gang loneuromas, 16 or 354, per cent sympathoblastomas (neuroblastoma) 2 or 2 3 per cent sympathogomomas and 2 or 3 2 per cent phe-ochromocytomas.

#### OCCURRENCE

Gray states that in 1864 Knoebellanch reported the first ganglioneuroma in the case of a neuroma reported by Other in 1803. The

From the Departments of Pathology and Surgery University of Michigan Homital, Ann Arbor Michigan.

tumor was undoubtedly a ganglion cell tumor The first tumor from the sympathetic nervous system to be adequately described was reported by Virchow in 1864, designated by him as a glioma but believed by Wahl and others to have been a ganglioneuroma. Loretz in 1870 first described ganglioneuromas and reported the first intrathoracic case. But it was not until 1910 that Wright placed these tumors on a sound pathological basis. He called attention to a group of tumors, the nature of which had previously escaped general recognition, and he pointed out their distinguishing characteristics. He considered the essential cells of the tumors to be more or less differentiated nerve cells, neurocytes or neuroblasts, and designated these tumors as neurocytoma and neuroblastoma. Paraganghomas or the chromaffin tumors were first described by Manasse in the suprarenal gland in 1893 Frankel in 1886 and Perley in 1890 described tumors apparently of this type.

True nerve tumors, i.e., growths consisting of specific nerve tissue elements, may occur in any part of the pervous structure. They may be benign or malignant and while they may differ widely in their structure, behavior and occurrence, vet they are closely related ontogenetically Both the benign and malignant forms are well illustrated in the sympathetic system. The benign form includes the gan glioneuromas and the chromaffin tumors, m both of which the cells are more or less highly differentiated. The malignant form, not recognized as such until Wright's epochal work placed them in their proper category are the neurocytomas or neuroblastomas. The confused terminology of this group will be discussed later

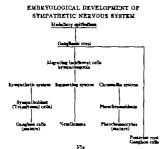

As previously stated, these tumors are as widely distributed in the body as the sympathetic nervous system litself but by far the greater number are to be found in the adrenal. Lewis and Geschickter studed 40 neuro-

HOLLINGSWORTH blastomas and found that 33 of them were in the medulla of the suprarenal gland, or in sympathetic ganglions adjacent to the medulla. Scott and Palmer reviewed the litera ture up to 1932 and found only 37 reported cases of sympathetic blastomatous tumors other than those in the adrenal medulla. Shultz in 1926 reported 53 cases of ganglioneuroma not in the adrenal The number of these cases found in the chest is not stated by either author Loretz's case in 1870 is the first thoracic sympathetic tumor reported Reid lists 3 cases of intrathoracic neuroblastoma and 6 of ganglioneuroma reported up to 1928 Bigler and Hoyne reporting I case of their own in 1934, reviewed the litera ture up to that time and found 11 reported cases in the thorax out of a total of 164 cases of ganglioneuroma in various situations James and Curtis found 33 reported cases up to 1941 and Skinner reporting 1 case in 1943 cites 37 in the literature Wahl and Robinson state that up to 1943 only 13 cases of thoracic neuroblastoma have been reported out of about 200 cases in the entire literature Para ganghoma are rare in adults and rarer in the chest, only 2 cases of thoracic origin having been recorded although Wahl and Robinson report an interesting case of a mediastinal neuroblastoma containing pheochromoblas tomatous elements EMBRYOLOGY

A thorough understanding of sympathetic nerve tumors is dependent on a knowledge of the embryology of the sympathetic nervous system According to Jordan the peripheral nerv ous system comprises nerves and ganglia out side the central nervous system. It includes (i) the cerebrospinal nerves and (2) the sympa thetic nervous system Constituent nerve fibers include both myelinated and unmyelinated varieties. The sympathetic ganglia of both the trunk and head arise from cells which migrate from the neural tube to their defini tive positions In the trunk region the gan glion cells migrate before the formation of definitive nerve fibers and during migration the cells are in an indifferent stage only later developing into either neuroblasts or support ing elements. It is well known that this

migration takes place at an early period of embryological development. In addition to the sympathetic neurocytes, the sympathetic primordium is also the progenitor of the chromaffin (pheochrome) cells In the early stages of development the two can not be distinguished from each other maffin cells are characteristic of the para ganglia the medulla of the suprarenal and the caroud body, although their presence in the latter is denied by some. The paraganglia are formed from groups of these cells which have migrated along the entire sympathetic system Some migrate to the dorsal surface of sympathetic ganglia where they form small rounded masses which become lodged in depressions in the ganglia. Other cells migrate to the kidneys uterus, liver and testes while still others come to rest on the ventral surface of the abdominal sympathetic plexuses and differentiate into larger chromaffin bodies The largest of these are the organs of Zucker kandl which develop in the connective tissue along the sides of the aorta near the bifurca The chromaffin cells of the suprarenal medulla pass laterally from the celiac sym pathetic plexus until they come in contact with the cortical cells which have developed from the celomic epithelium The medullary cells then grow into the mass of cortical cells this growth beginning at about the 12 milli meter stage and continuing until after birth. According to Poll the development of gan glion cells from sympathogonia continues until the tenth year and this may be a factor in the development of neoplastic conditions of the sympathetic system These peripherally migrating nerve cells may come to rest almost anywhere in the body and are capable of proliferating and forming tumors at a later date in life

Experimentally the origin of the sym pathetic system has been proved by Harri son's historic work and confirmed by Van Campenhout They showed that the removal of the entire neural crest from embryo Rama pipens will result in total failure of development of the spinal and sympathetic ganglions throughout the trunk region The motor neurons develop normally but are sheathless the chromaffin apparatus of the adrenal gland

does not develop and there are no sympathetic nerve elements in the wall of the digestive tube.

A critical examination of the sympathetic primordia shows these elements to be totally undifferentiated. They are spherical in shape and possess round chromatin rich nuclei sur rounded by scant cytoplasm. These cells have often been described as lymphoid cells and it is this 'lymphoid characteristic which undoubtedly led early observers to describe tumors composed of these cells as small round cell sarcomas or lymphosarcomas. Even at this early stage according to Bielschowsky these sympathogonia or undifferentiated neurocytes possess very delicate fibrils which are not as yet demonstrable by the silver staining method. Passing along to the next stage of maturation sympathogonias develop into sympathoblasts which are somewhat larger than the former possess a clearer almost vesicular nucleus and a somewhat larger protoplasmic body. In part they produce axones which may be demonstrated by the silver method in the form of fine threads and may be traced over long distances. The final stage of maturation is represented by the sympathetic ganglion cells in which the nucleus-plasma relation is largely in favor of the cell body The cells possess predominantly a multipolar form and exhibit a varied manner of branch ing of their processes. They contain intra

cellular fibrils and chromophile Nissl clumps. These nerve cells are enclosed in a connective tissue capsule and are surrounded by gluogenic satellites.

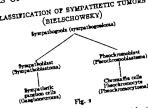

The embryogenic factor of importance in the understanding of the histopathological findings in sympathetic neoplasms is the role played by the sympathogonia. They have been assigned a place in the scheme of development comparable to the rôle of the medulloblast in the developing central nervous system. Schaper was the first to hypothesize indifferent cells, derived from the medullary epithelium, bipotential in their possibilities, and developing into either spongloblasts or neuroblasts. While many workers deny the existence of the medulloblast. His accepted these cells but he did not believe them to be bipotential He believed, rather that each cell was unspotential and was predestined from the beginning to become a spongloblast or a neuroblast Bailey and Cushing believed that Schaper's hypothesis was necessary for a proper comprehension of the normal histogenesis of the brain of malformations of the brain and of brain tumors. Having been generally accepted this theory is likewise essential to a proper understanding of the developing sympathetic nervous system and its abnormalities. Sympathogonia, then, are generally considered as indifferent cells, pluripotential in their possibilities and the mother cells of (a) sympathoblasts and sympathetic ganglion cells (b) the chromaffinic (pheochromic) cell structures which are the pheochromocytes of the adrenal medulla, the paraganglionic bodies and other structures and (c) the immature glial cells of the sympathetic nervous system, the astroblasts, which ripen into mature supporting units, the astrocytes. The genetic elements comprising the sympathetic nervous system are ex pressed schematically in Figure 1

Martius in 1913 described a tumor in which he found both a high degree of differentiation of the fibrillae and the presence of many cells that corresponded to Poll's sympathoblastic He called this tumor a sympathoblastoms and looked upon it as affording the missing link between gangloneuroms and the malignant reumblastoms.

### CLASSIFICATION

Inasmuch as it has been demonstrated that the sympathetic nervous system is developed by a progressive growth of and a differentia tion from the pluripotential mother cells, the sympathogonia, it is to be expected that tumors arising during the process of differ entration may contain cells in varying degrees This naturally produces new growths difficult of classification, as the of maturity tumors rarely contain a single cell type. Various transitions between different forms have been reported and two or three types may be present in one tumor classifications have been offered and even a casual review of what has been written on the subject serves to convince the reader of the confusion which exists. Wahl in 1914 Dunn in 1914 1915 Lehman in 1927 Symmers in 1936 and others have classified cases as neuroblastomas ganghoneuromas and chromaf finomas. Von Fischer in 1922 classified the group according to degree of differentiation Scott and Palmer in 1932 base their classifica tion on the plan proposed by Balley and Cushing for tumors of the central nervous system Bielschowsky believes that a simple classification is best and that any attempt to subdivide on a basis of degree of immaturity only adds to the confusion and his classifica tion is the simplest one found Robertson in 1915 correlated the terms used by previous authors. Neurocytoma (Marchand) = neu roblastoma (Wright) = sympathoblastoma ganglioma embryonale sympathicum (Pick) = sympathogonioma (Kohler) = sym Bailey and Cushing prefer the term sympathicoblast for the primitive pluripotential cell before it has taken on the characteristics of a unipolar neuroblast and they use the term sympathicoblastoma instead of neuroblastoma for all tumors in which the cellular elements are of the undifferentiated type They feel that sympathicoblastoma more definitely places

these tumors because the term neuroblastoma is used also to describe certain cerebral neoplasms. Further all the primitive cells are not potential neuroblasts since some differ entuate into chromaffin cells. On this basis Blacklock classifies all cases, exclusive of the

chromatinomas, into sympathicoblastomas (all malignant) and ganglioneuromas (generally simple and benign) The former he subdivides into (1) undifferentiated (com posed only of sympathogoni) and (2) differ The differentiated be again subdivides into those which are composed of sympathogonia and sympathoblasts and those containing ganglion cells in addition to the more primitive cells. These he terms gangliosympathicoblastoma From a practical clinical and pathological point of view Biel schowsky s simple classification is appealing Schematically it is represented in Figure 2

Bielschowsky makes no attempt to subclassify the tumors according to the various degrees of differentiation as is done by some authors. As has been repeatedly stressed, these tumors are composed of more than one cell type and a thorough understanding of the embryology with the designation of the neoplasm according to the predominant type of cell present, should serve to give one a clear picture of the pathological process

### DISCUSSION

A discussion of sympathetic nerve tumors on a basis of any of the various classifications available is very difficult. However from a review of all available descriptions of the microscopic appearance of the reported tu more I believe that the names neuroblastoma, sympathoblastoma, and sympathicoblastoma have been used interchangeably to designate the immature type of tumor Usually no attempt has been made to separate these im mature tumors into those composed entirely or predominantly of sympathogonia (sympathogonioma), and those in which the

sympathoblast (sympathoblastoma) in various degrees of maturity is the predominant cell. The present discussion follows Biel schowsky's simple classification (Fig. 2)

Sympathogonioma As is to be expected the sympathogoniomas are very malignant. Found most commonly as a primary growth in one or both adrenals, their occurrence in the chest is rare. Saller and Andrus having reported the only cases. However taking the factors mentioned in the preceding paragraph into consideration one is rustified in assuming that other sympathogonioms are present in the group reported as neuroblastoma or symnathoblastoma. The case reported by Startz and Abrams is an example. This was a 2 year old child who died and at autopsy extensive metastases to the lymph nodes and bones were found. Microscopically the tumor was composed almost entirely of small round cells with scant cytoplasm, typically sympathogonia. Because of their highly malignant nature they are found most commonly in the newborn and in youth rarely in adults. Paradoxically enough, Sailer's case was in a woman of 65 vears of age

Sympathogonioma are extremely cellular being composed of the closely packed lym phoid type of cell previously described. Very little supporting structure is seen. There is a tendency to rosette formation, Lewis and Geschickter having found rosettes in onehaird of their cases and Wahl reporting them in one-half of the cases studied by him. Metastases usually occur early and are widespread, being found most frequently in the

lymph nodes long bones, akull brain, and

Sympathoblasioma Sympathoblastomas. differing only in that they represent greater maturity are somewhat less malignant and usually are found at a somewhat older age. Scott and Palmer reporting on 13 sympathetic tumors other than those in the adrenal gland found that 5 or 38 per cent, were in children 3 years old or younger #4 compared to 11 or 58 per cent, of 19 sympathogoniomas in the same age group. Intrathoracic sympathoblastomas are rare occur ring in only 16 of the 63 cases of sympathetic nerve tumors found recorded to date an incidence of 25 5 per cent. This includes the case of Wahl and Robinson which contained pheochromoblastomatous elements and Cushing and Wolbach's case which was of the dumbbell type the intrathoracic portion being a sympathicoblastoma and the intra spinal portion (removed to years after the intrathoracic operation) a ganglioneurona. The age limits were from 12 weeks to 48 years, 12 of the 16 cases or 75 per cent occurring in children under 10 years of age

Blacklock states that no tumor composed only of sympatholasts has yet been reported. While these cells usually predominate in the over-all picture sympathetic ganglion cells and all degrees of differentiation are encountered. Sympathogonia, sympathoblasts, immature ganglion cells, and mature ganglion cells may be present in one section. On the other hand, sections from different parts of the same tumor may present only one cell type sod unless blocks are cut from various parts and studied an entirely erroneous diagnosis may contend the sympathobe made Not as cellular as the sympathobers of nerve fibrils Differential stains such bers of nerve fibrils Differential stains such connective tissue stains are often necessary for complete classification Metastasizing much more slowly than the sympathogonioms they are more apt to show local invasive tendencies. Their metastasizing tendencies, however are as varied as their microscopic

Ganglioneuroma Passing on to the mature picture tumors we have the ganglioneuroms. In these the neurocytic elements have differentrated into ganglion cells rich in plasma. Con trary to the opinion expressed by Bohrer and Lincoln this tumor is far from rare among children Shultz reported 53 cases of ganglioneuroma not in the adrenal gland Twenty four were in adults, 21 in children and in 8 the age was not stated In the intrathoracic cases the age varied from 1 to 73 years 21 out of 43 cases or 48 8 per cent, being 10 years of age or younger and 29 or 67.4 per cent, under 20 In 3 additional cases the age is not given although one is stated to be a child In none of these tumors however, can age per se be said to be of great importance as all are due to embryonic rests, the age given representing only the age at which they are discovered Sex also is unimportant, 12 of the cases being in females 11 in males and in 6 the sex was not stated (Table 1)

Ganglioneuromas vary in size the reported tumors ranging from that of a hen segg to that of a child a head Usually of firm consistency and well encapsulated, degenerative changes may give the tumor a soft feel beneath a firm outer shell The cut surface may show lobulation and its color varies according to the degree of vascularity Usually they are relatively avascular and present a grayish white to gray glistening appearance Microscoplcally the picture is usually one of rather coarsely arranged fibrous tissue mixed with strands of medullated and nonmedullated nerve fibers the latter predominating as a Multipolar ganglion cells in varying numbers are found scattered throughout

Some areas may be very cellular while in others only an occasional ganglion cell is seen. These areas vary not only in different tumors, but in different parts of the same tumor. Not but in different parts of the same tumor. Not infrequently multinucleated ganglion cells are infrequently multinucleated ganglion cells are year indicating an element of immaturity seen indicating an element of immaturity and in a growth which otherwise has all the criminal growth which otherwise has all the criminal ganglion neurofibroma or ganglionated name ganglion neurofibroma or ganglionated or ganglionated and ganglion ganglionated in the ganglion ganglionated in the ganglion ganglionated in the ganglion gan

article represent this type
Usually considered as benign tumors malig
nant ganghoneuromas have been reported
These are due to an abundant intermixture of
immature ganghon cells and have been
designated as ganghoneuroblastoma.

which Lewis and Geschickter consider the most common tumors of the sympathetic system are exceedingly rare within the thorax only 2 cases having been reported that of Miller in 1924 and Phillip's case in 1940 The case of Wahl and Robinson previously mentioned did contain chromaffin elements although the authors classified it as guishing feature is, of course their affinity for a sympathoblastoma chrome salts The large polyhedral cells in a richly vascularized fibrous tissue stroma show a granular cytoplasm and a large vascular nucleus usually containing one large nucleolus Sections fixed in Orth's solution which contains potassium dichromate stain the cytoplasmic granules a golden yellow

Dumbbel immors Tumors which present both in the chest and in the spinal canal, the so called dumbbell or hourglass tumors, have been described. They are of fairly frequent occurrence, particularly among the ganglioneuromas. While an intrathoracic growth may conceivably grow into one or more of the vertebral foramina, I believe that these tumors are more accurately accounted for on an embryological basis, either from an embryological basis, either from an embryological basis, either from an em an embryological basis, either from an em an emtrostal nerve. Quite frequently it is the pressure of the spinal segment of the tumor

on the cord which brings the condition to the attention of the patient. They are found more frequently in children. Eden in his paner devoted to this type of tumor reports an interesting case of a man 23 years of age whose first symptoms dated back to age 5 when a radiographic opacity in the chest had been diagnosed as an irremovable sarcoma of the spine During the intervening 18 years, he had been free of symptoms but finally presented himself for treatment because of leg weakness and difficulty in urinating the same symptoms which had called attention to the tumor many years before At operation the tumor was found to be a ganglioneuroma, dumbbell type

Unusual types Martius (quoted by Dunn) in 1013 described a case in which a malignant neuroblastoma was removed surgically from the lower part of the neck, and, on subsequent postmortem examination another part of the same tumor in the uppermost part of the thorax was found to be a ganglioneuroma Furthermore Suzuki 1910 Hedinger 1911 and Wahl 1914 have reported cases in which sympathogonia ganglion cells and chromaf fin cells were all present in the same growth. Wahl and Craig have also found that these tumors may be multicentric. While usually of the same type, all three types (neuroblastome ganglioneuroma, and paraganglioma) may be present, occurring independently of each other. They report a case of a 28 year old man in whom three separate growths were found (1) a ganglioneuroma of the sigmoid colon (2) a neuroblastoma in the pelvia and (1) a ganghoneuroblastoma in another part of the pelvis. The only multicentric tumor involving the chest is that reported by Bigler and Hoyne, a mediastinal ganglioneuroma with another located under the right clavicle

Acusofibromas Finally one must not lose sight of the fact that any of the intrathoracic neurogenic tumors may have their origin from the sympathetic nervous system. In speaking of sympathetic nerve tumors, one instinctively thinks only of the immature and mature ganglion cell tumors aiready described. However reference to Figure 1 clearly indicates that all the neurogenic elements found in the neurofibromas schwanomas etc. are de-

rived from the ganglionic crest. In addition to this, even though the neoplasm may grossly appear to originate from an intercostal nerveit must be remembered that intercostal nerves are derived partly from the ganglions of the posterior roots, which ganglions arise from the medullary epithelium by way of the neural There are two schools of thought regarding the origin of neurofibromas, one group who note the presence of collagen and reticulm fibers and regard them as true mesoblistic fibromas, and the second group who trace all the tumors to neural elements, especially the Schwann cells, endoneurium and the lamellar sheath. In either case they may be derived from the sympathetic system and thus subject to classification under this heading. In this connection, a recent case report by Blades and Dugan is of interest. Two neurofibroms were found on the upper sympathetic chain within the thorax and 2 on the left vagus below the recurrent nerve. In addition, this patient had café au last spots in both axillae and on the chest, typical stigms of you Recklinghausen a neurofibromatosis. Removal was without incident. In spite of the definite possibility of their sympathetic origin, no classification has yet been offered which makes provision for the inclusion of this large group of tumors. In fact, they are not usually considered as sympathetic nerve tumors. The increased incidence of the removal of intra thoracic neurogenic neoplasms will undoubt edly stimulate further study of these growths and lead to a more accurate classification.

#### CASE REPORTS

Seven cases of intrathoracic sympathetic nerve tumors have been found in the records of the University Hospital and they are reported somewhat in detail here

CARE I. E. L. B. No. 377134. a year old school control was admitted to the University Hospital on October 4s, 1906 Best. Head correlative was pain in October 4s, 1906 Best. Head correlative was pain in the control october 1906 Best. Head of the pain begin about 196 years previously and had increased gradually up to the time of admission. For the past year there had been abortness of breath on carrition and she had falled to gain weight. One menth perviously she had had an unexplained period of fever up to 103 degree and an x ray film of the chest disclosed a tumor in the left hemithous. Essential physical finding were heart displaced to right, the right border of

HOLLINGSWORTH cardiac duliness being I centimeter medial to the right nipple line and the left border of cardiac dull ness shaded into the flatness of the lower part of the left chest. Heart sounds were normal The left chest was flat to percussion below the left second rib anteriorly the fourth rib in the axilla, and the fifth and sixth posteriorly Below this line breath sounds were absent. Tactile and vocal fremitus were absent In the abdomen fullness was demonstrated in the left upper quadrant and the spleen could be palpated below what appeared to be a tumor mass. The Kahn reaction and all routine laboratory tests were within normal limits The vital capacity was were within mirman minus and vital capacity was 675 cubic centimeters congulation time 6 minutes 7187 examination revealed a gross tumor mass in the left upper abdomen and lower thorax apparently displacing the spleen and kidney down and the displacing the spleen and kidney down and the displacement of the mass was predeminantly posterior There was no evidence of skeletal involvement. Deep x ray therapy had been given without benefit elsewhere before admission. Operation was performed on October 28 1935 by Dr John Alexander Removal of a firm tumor which was retropleural and attached to the entire upper surface of the diaphragm and to the entire anteroposterior diameter of the mediastinum except in the far anternor portion. Only moderate bleeding oc curred all of which was relatively easy to control Patient withstood the operative procedure well but died I hour postoperatively of hemorrhage

Pathological report No 2902 AN A large encapsulated tumor 17 by 12 by 5 centimeters, weighing 1150 grams. Smooth surface lobulated on one side. On cut section surface is yellow gray Microscopic

CASE 2 B L. No 472537 a white gitt, aged 8 years was admitted to the University Hospital on diagnosis ganglioneuroma January 8 1941 This patient apparently had no symptoms referable to the chet. She was seen discountries to the chet. where in December 1940, with the complaint that during the past 4 years the feet had become deformed and interfered with walking She had a pes equinus deformity In the course of her check up examination a chest x ray film was made and showed a complete opacity of the left hemithorax with displacement of the heart and mediantinum to the right. In the standard films, it was impossible to differentiate between a massive tumor and fluid. Later grid films showed a well carcumscribed encapsulated mass in the posterior portion of the encapsulated mass in the posterior portion of the left hemithorax. There appeared to be numerous flecks of calcium within the mass At fluoroscopy it was felt that the mass contained fluid and a thora centesis was done but no fluid was obtained. Fol lowing the thoracentesis there was a sharp rise in temperature to 103 degrees and the pulse rate reached 160. Two days later an exploratory thor acotomy was done and the bropsy material obtained revealed a ganglioneuroma. The child was then sent to the University Hospital for removal of the tumor The past history was noncontributory except for the fact that the child had had measles with a com-

plicating pneumonia 2 years previously She was picating precurrous a years pictured and never really well after this, being nervous and never really well after this, being nervous and irritable and had a poor appetite. The physical examination showed only a poorly nourished girl of 8 years with a pes equinus deformity of both feet No other abnormalities were noted except in the chest where the findings were compatible with the lesion revealed by the x ray examination Routine laboratory tests were within normal limits. The

Operation was performed February 14 1941 by Kahn test was negative. Dr Cameron Haight. The chest was opened through the usual posterolateral incision. The tumor mass exposed was a very firm one In the scapular line the subjacent tumor was adherent to the parietal pleura but in the anterior axillary line a free pleural space was present. The anterior portion of the tumor was not adherent to the lung which was crowded into the anterior portion of the pleural cavity The sixth intercontal nerve entered the capsule. The tumor extended from the third rib posteriorly to the disphragm. Deep fingerlike processes of tumor extended into the eighth ninth and tenth inter costal spaces adjacent to the spine. The mass was removed by blunt and sharp dissection and at about the time it was removed respirations suddenly ceased Only a limited autopay was obtainable and from this it was impossible to determine if the spinal canal had been invaded by the growth No regional metastases were present. Grossly this was a large oval-shaped encapsulated tumor presenting ir regular nodes on the surface and on section a uniform waxy and fibrous, yellowish tissue weight was 595 grams and it measured 16 by 10 by 614 centimeters

Microscopic examination pathological report No 4305 AS The tumor is made up of counties large ganglion cells which frequently contain two or more nuclei and numerous bundles of peripheral nerves lying in a dense connective trisue stroms and showing areas of secondary calcification and peri vascular inflammation Diagnosis peripheral gan glioneuroma.

This was a typical ganglioneuroma showing a relative amount of unmaturity as evidenced by the frequent multinucleated ganglion cells seen

CASE 3 T O No 486332 white schoolboy aged 11 years was admitted July 31 1941 This boy had no symptoms either past or present as a result of the neoplasm present in his chest. A routine tuberculin test at school in May 1941 was positive and for that reason a chest x ray film was made showed the presence of a tumor mass in the left hemithorax. On admission, physical examination was negative except for the chest There were diminished breath sounds at the left aper, extending down to the second anterior rib There was im paired resonance but normal fremitus over this area o rales were heard Posteriorly there was duliness

diminished breath sounds, and whispered volces sounds down to the sixth rib The blood Kahn reaction was negative and all routine laboratory tests were within normal limits. X ray examination of the chest showed a rounded mass in the upper portion of the left hemithorax extending as low as the anterior portion of the lithir interpret. Some crossion of the posterior portion of the third rib was visualized. Oblique and lateral views showed the large mass to lie far posteriorly and adjacent to the vertebral column.

Operation was performed on August 1 1041 by Dr John Alexander The approach was posterolateral through the bed of the fourth rib with resection of about 6 centimeters of the third rib A slightly soft and completely encapsulated peoplasm was found in the costovertebral gutter extending from below the dome of the pleural cavity to the level of the fifth posterior intercostal space. After dividing the parietal pleura around the base of the tumor it was readily removed by blunt dissection, the removal including a lobulation which projected into the mediastinum. The pedicle of the tumor appeared to be at the level of the third intravertebral foramen and the third and fourth transverse proc esses were removed to expose this foramen. tumor was seen to traverse this foramen, which was larger than normal. Portions of the lamina were removed and at a depth of 1 < centimeters in the foramen, the tumor was seen to taper off to a point and was removed completely Recovery was uneventful and the patient left the hospital on the sixteenth postoperative day He has remained entirely well to date.

Pathological report, No 666 AT Microscopically routine hematoxalin and cosin stained slides show a strong having the appearance of a neurofibroma and containing large numbers of typical ganglion cells. Diagnosis, ganglionated neurofibroma

This was another case of a rather large tumor which was symptomless and discovered only accidentally. It was almost a dumbbell type extending for a short distance into the intervertebral toramen.

CASE 4. K T No 436736 white boy aged 13 rears, was admitted December 3 943 This patient had no chest symptoms. A short time before this admission he had had a fall and x ray films of his shoulder were made. These revealed an intra thoracic neoplasm and he was referred to the Uni versity Hospital for its removal. The rest of the history is noncontributory except for the presence of a long standing and very extensive ecsema. Physical examination showed very little. There were some palpable enlarged lymph nodes in the neck and both axillae. A diffuse dry scaly ecsema was noted over the greater part of the body and extremities. There were duliness t percussion and diminished breath sounds over the upper left chest both anteriorly and posteriorly The rest of the examination was nega

tive. The blood Kahn reaction was negative and other routine laboratory examinations were within normal limits. X ray examination of the rheat revealed a fairly extensive homogeneous observeries of the upper portion of the left bemithour, more marked in its median aspect. Films of the dorsal spine revealed extensive erosion of the upper doral vertebral bodies. The erosion beam at the level of second dorsal vertebra and extended downwards as far as the sixth dorsal vertebra. The left lateral and posterior aspects of the vertebral bodies were involved and the abnormality was in the form of scalloping of the margins of these bodies. There appeared to be associated widening of the anterposterior diameter of the spinal canal in the region of the vertebral erosion and there was also associated erosion of the vertebral and posterior portions of the third, fourth and fifth ribs.

Operation was performed December 10, 1043 by Dr John Alexander A posterior approach was used with the incision extending from the second rib over the sacrospinalia muscle downward to the seventh rib and laterally beyond the inferior angle of the scapula. On the posterior surface of the sacrospinshi muscle from the level of the third to the fifth posterior ribs a neurofibromatous lesion was visible. This lesion in the muscle was completely removed, together with the adjacent muscle tissue. This had a vertical length of approximately 4 centimeters and a borisontal width of approximately a centimeters. This was later seen to have arisen from the main tumor mass at the level of the extreme posterior third intercostal space. It was necessary to remove, subperferteally the posterior to centimeters of the fourth, fifth, and sixth ribs. Also the head and neck of the fourth rib were removed so as to give manimum exposure of the third and fourth intervertebral foramen where the tumor times was applied snugly to the foramen. The tumor appeared to be attached to the third fourth fifth, and sixth intercosts! nerves at their emergence from the intervertebral foramens. By blunt and sharp dissection the tumor was finally removed from its bed Usual closure without drainage. The postoperative period was rather stormy and a left-sided empyema had to be drained on the fifteenth day. The ultimate recovery was complete however and the present condition is excellent

Pathological report No 246 AV Hematamias and each stain, sections show large fragments of a membranes. See 16th earth of the strong is educations and company to the strong is educations and the strong is education and the neurophoromatous clements. There was no invasion of the attached muscle and bone fragments. Diagnosis, sensitionated and bone fragments. Diagnosis, sensitionated enerophyroma.

Diagnosis, ganglicosted neurolibroma.

Cast § 1 S. No. scrool white maie, and 19 years, was admitted to the University Hospital 194 6 1044. The chief complaint was extreme dysposition March, 1944, be began to have pain in the right chest which persisted to date. In addition there were couple and ferrer the temperature rising to 103

degrees. Cough was productive and the sputum was streaked with bright red blood. The fever lasted for weeks and then returned to normal. The condition was disgnosed as pneumonia. Although the other symptoms subsided the pain remained and an x ray examination of the chest was made. It revealed a "tumor of the right lung Eleven deep x ray ther apy treatments were given without effect. The pain gradually became more severe. It was both dull and sharp. Worse in the right chest it radiated at times to the right arm. The amount of sputum increased until it totaled about one-half cupful a day. It was purulent but not foul. For the week before ad mission there had been some edema of the feet and ankles. Because of the pain and dyspnes, the patient could not lie down. On admission he was in extreme dyspnea and mildly cyanotic. During the 4 days before operation he was kept constantly on intranasal oxygen The Kahn reaction was negative and all routine laboratory procedures were within normal limits.

HOLLINGSWORTH

Operation was performed by Dr John Alexander on July 20 1944 When the chest was opened a large tumor was found filling the upper half of the right hemithorax. Its size was estimated as about 12 by 12 by 12 centimeters. The right lung was displaced downward and the upper mediastinum to the left. The tumor was "frozen to the mediastinum and to the spine. Removal was impossible. It was impossible to determine whether the mass was merely frozen to the mediastinum and spine or whether it was infiltrating these structures. The inside of the tumor was completely degenerated. The degenerated inner portion of the mass was evacuated and about 52 per cent of the wall was removed in order to relieve the pressure on the traches and great vessels of the upper mediastinum. Dyspnes was greatly improved Recovery was uneventful there being one thoracentesis for the removal of a few hundred cubic centimeters of fluid. He was discharged on the thirteenth postoperative day. The subsequent course was downhill and death was reported to have occurred within a few months. There was no au

Pathological diagnosis No 100 AW Sympathoblantoma

CASE 6 J L. N No 562795 white schoolboy aged 16 years had neoplasm producing no symptoms. The tumor was discovered when a chest x ray film was taken at school in a routine tuberculous survey He was then referred to the University for surgical treatment. The past history was noncontributory The physical examination was negative except for the chest. Posteriorly there was increasing duliness to flatness from the second rib down to the seventh Decreased breath sounds over this same area. The blood Kahn reaction was negative and all routine laboratory tests were within normal limits. A ray examination showed a large mass which was fairly smoothly rounded anteriorly and which lay in the posterior portion of the left hemithorax and extended from the level of the third or fourth dorsal vertebra as far down as the tenth dorsal vertebra. This mass was of homogeneous density and in lateral view it was seen to lie far posteriorly. There was consider able bony architectural change. This consisted of abnormality of the structural character of the fourth, fifth, and sixth vertebrae. There was sug gestive evidence of widening of the neural canal between fifth and sixth dorsal vertebrae and definite abnormality of the left sixth and seventh ribs posteriorly There was what appeared to be loss of vertical height of the sixth dorsal vertebra in the anteroposterior view and in the lateral view there appeared to be some loss in vertical height of fifth dorsal vertebra and possibly also of the seventh. In addition the intervertebral disc space between the fifth and sixth dorsal vertebrae was not easily identified and the pedicle on the left of the fifth dorsal vertebra appeared to be absent. In part, the changes appeared to be due to erosion, probably due to pressure, and in part they may be due to con genital malformation. The changes did not suggest invasion of the vertebra by neoplasm

Operation was performed by Dr. Cameron Haight on February 10 1945 The approach to the tumor was posterolateral through the bed of the resected fifth rib The large tumor mass was partially adher ent to the parietal pleurs and it occupied the nos terior half of the chest at the level of the resected rib The lung was crowded forward by the tumor The tumor was of a firm consistency and had a vellow color. On its surface were scattered areas of organ ized fibrin. The tumor was removed by blunt and sharp dissection. During its removal it was seen that the sympathetic chain and the fifth and sixth intercostal nerves were all either incorporated in or attached to the mass. They were removed with the mass. After the removal of the tumor it was seen that a nodule projecting from the surface of the tumor had caused an erosion of the fifth intervertebrai foramen and had exposed the epidural veins over an area of about 1 5 centimeters. Recovery was uneventful and the patient left the hospital on the thirteenth postoperative day

Pathological report, No 3853 AW The specimen consisted of a grapefruit sized, well encapsulated mass which on section had a firm, whitsh appear ance. Microscopic, a large neurofibroma with a few ganglion cells. Diagnosis ganglionated neurofibroma

CASE 7 D S No 564033 was admitted February 14 1915 This 2 year old boy was seen first in the Department of I editatres. He had been in perfectly normal health until 4 week before admission at which time the mother noticed that he dragging his right left leg. Soon afterward he began dragging his right left leg. Soon afterward he began dragging his right leg also and them crased to walk entirely This condition progressed rather rapidly until he soon was unable to sit up but he complained of no pain. The mother noticed however that there was in creased urificability. There was no incontinence of urine or feces. Two weeks before admission he was seen elsewhere and a diagnous of spinal cord tumor

was made. He was then referred to the University Hospital for treatment. Physical examination re vesled a well developed white boy who did not appear acutely III but who was unable to walk or sit up. All findings, including funduscopic examination of the eyes were negative except the following Extremities showed bilateral paralysis of the legs. The patella reflexes were greatly hyperactive. The right leg offered some resistance when bent. The ankles were quite stiff. The left leg responded markedly when the Babinski test was tried. The right responded with spreading of all toes on trial of the same test. There was no diminution of pain sense. The blood Kahn test was perative as was the tuberculin test All other routine laboratory exami nations showed results within normal limits. X ray examination of the chest revealed a huge solitary well defined tumor occupying the left upper chest with displacement of the mediastinum to the right. Finely dispersed calcification was present throughout the mam. Detail films of the spine showed no abnormality

A lumbar puncture was done on the day after admission and bloody spinal fluid was obtained

There was evidence of a partial block.

The child was seen in consultation by the depart ments of neurology neurosurgery and thoracic surgery It was agreed that the first attack should be directed toward removal of the spinal cord pressure, after which, removal of the intrathoracic portion of the mass would be attempted. The child seemed to remain perfectly well until February 26 at which time he developed a cough and evidence of an acute bronchitis In spite of vigorous treatment he developed increasing respiratory difficulty and died on February 27

Autopsy report. Only the pertinent facts pertaining to the neoplasm will be recorded here. All other findings were essentially normal and no evidence of metastases was found "In the left pleural cavity is a neoplasm measuring 10 centimeters in diameter It is round. There are numerous widely dilated blood vessels coursing over the surface of this neoplasm. The surface is a dull reddish-purple in color and elistening. It is firmly attached at the upper pole to the apex of the left pleural cavity by firm fibrous adhesions. It somewhat compresses the left subclavian artery which courses over its superior surface. There are several pale, white, oval bodies attached to the superior surface which appear to be lymph nodes infiltrated by neoplasm. Posteriorly the neoplasm is attached by fibrous adhesions to the second, third and fourth ribs and so firmly at the root of the second and third that portions of these ribs were removed in order to facilitate removal of the neoplasm. Medially it is attached to the first, second third, and fourth dormal vertebrae, again by firm fibrous adhesions. These vertebral bodies were removed with the tumor and, although the tumor was perfectly encapsulated in other areas, it appears to have invaded the spinal canal at the level of the second and third spinal foramina, extending along the spinal canal for a distance of about a coulmeters and forming a mass within the canal anproximately 1 5 by 1 centimeter in diameter with somewhat compresses the cord, although it does not appear to have infiltrated it. On cut section of the tumor the cut surface is a dull white in color and is moderately firm. There is a medial area which appears somewhat whorled is firm in consistency and is a grayish-white in color " Weight 180 gram.

Microscopic examination revealed many connective tissue fibers showing whorled sress, namerous scattered ganglion cells, areas of calcification. The portion which invaded the spinal canal has a similar appearance. The nodules on the superior surface of the tumor are similar to the neophian, with no evidence that they arose in lymph nodes. Diagnosis, ganglionated neurofibroms.

This case appears to have been a rather rapidly growing ganglioneuroma of the dumbbell type causing paralysis and then death from spinal cord pressure

# PH ONIDAL CYST

# Analysis of 100 Consecutive Cases Emphasizing Treatment by Radical Excision Primary Closure and Penicillin Therapy

LEO C. LARKIN M D., Lieutenant Commander M C., U.S.N.R., Oak Park, Illinous

T is the purpose of this paper to present a series of 100 consecutive cases of patients with pilonidal cyst (sacrococcy geal cyst teratoma U S Navy nomen clature) operated upon by the author between January 15 1045 and July 30 1045 A new previously unreported method of treatment has been used with results that are believed to be unusual

Eighty-seven of these patients were operated upon by a technique of radical dissection and primary closure to be described and the plentiful use of intramuscular penicillin ther any In 75 cases, healing occurred per primam by the 7th postoperative day The series includes 34 patients with recurrences who had previously been operated upon elsewhere and 66 patients who had not been operated upon prior to admission to this proctology service Of this latter subgroup which proved most amenable to radical excision and primary closure in 60 cases out of 66 or oc o per cent bealing was firm by the 7th postoperative day

The technique employed consists of four

principal features

r Careful preoperative preparation and the routine use of preoperative and postoperative

nenicillin therapy

- 2 Excision of a minimum strip of skin sufficient only to include the ostin of the cyst undermining of the skin, removal of the cyst en bloc and the radical excision of the surrounding fat thus exposing the sacrococcygeal fascia and the gluteal fascia bilaterally to assure removal of all cystic tissue
- 3 Accurate reapposition of the skin and use of wire through-and through sutures in-

This article has been released for publication by the Division of Pathentions of the Burnars of Medicine and Sengary of the U.S. N. vy. The opinions and views set forth are those of the writer and are not to be considered as reflecting the policies of the N. vy beautiful.

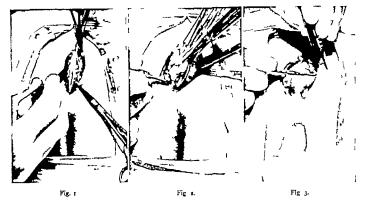

From the Department of Proctology U S. Naval Hospital, Great Lakes, III.

serted to the outer limits of the wound and underneath the sacrococcygeal fascia. The latter sutures are twisted over rolled game dressings and sponge rubber thoroughly to obliterate dead space

Avoidance of the use of any drum or per manent suture in the wound and the removal of all sutures on the 7th postoperative day leaving no foreign body in the wound, thus allowing for a minimum of scar tissue and the restoration of the normal intergluteal fold, without skin tension.

For the sake of presentation and review of cases, the series is divided into three subgroups, the criterion for which was, on admosion and at operation the feasibility of primary closure in each case as determined by the condition of the skin overlying the cyst-That is, whether it was intact except for the embryologic ostra (Subgroup 1) scarred by previous operative procedures and containing artificial ostus but not unduly sacrificed (Subgroup 2) or markedly depleted, scarred, and stretched by previous block excision (Sub-

eroup 1) In Subgroup 1 consisting of all the patients (66) who had not been previously operated upon and who were treated by primary dosure healing per primam occurred in 60 cases, or 90.9 per cent. In Subgroup 2 consisting of 21 patients who though previously operated upon appeared amenable to primary closure successful primary healing was obtained in 15 cases or 71 per cent. Subgroup 3 connested of 13 patients who had been previously operated upon elsewhere two or more times. In these patients primary closure was not attempted because of the marked loss of skin and scarring present. Partial closure was carried out, as will be described in an attempt to cut down the disability time to a minimum

The surgical treatment of pilonidal disease by primary closure has always presented well known problems the most important of which are infection which frequently nullifies the results after the best of surgical techniques and the mechanical problem of closure of the wound without tension after thorough exci sion of the cyst and obliteration of the dead space The sacrococcygeal area is readily contaminated before and after surgery be cause of the proximity of the anus and the tendency for the skin to be moist by perspira tion The skin over the sacrococcygeal area is readily traumatized and is stretched in sit These factors make any postoperative wound vulnerable long after healing has taken place (27) and make it imperative that sound healing be obtained by complete obliteration of dead space by the avoidance of the use of permanent sutures which act as foreign bodies and by use of a technique which does not sacrifice the vitally needed skin overlying this area

The needless sacrifice of skin over this area attendant upon block dissections which include the skin and its ultimate replacement in healing by inclastic scar are at least as great a cause of recurrence due to faulty healing as is the failure to obliterate dead space (22 28)

It is an unfortunate fact that when elliptical incisions are made on either side of the inter gluteal fold the maximum loss of skin occurs where it is most needed in the primary closure of the wound—in the widest diameter over lying the glutea. When primary closures are attempted after elliptical excision of the skin a flattening of the intergluteal fold results—producing a painful scar that is constantly stretched and traumatized (27) when the patient assumes the sitting position

The technique herein presented deals with the problem of infection by adequate pre-

4 fie

operative preparation atraumatic surgery and the unstituting use of pencillin therapa. The second problem that of closing dead space avoiding the loss of skin and maintaining the normal intergluteal fold is met by the following expedients.

- 1 The avoidance of the use of permanent sutures in the wound that may later set up foreign body reaction
- 2 The closure of the dead space, accomplished by the use of multiple, deeply placed wire through-and through sutures that encompass the wound and include the sacrococcygeal fascia. These are later tied over gauze rolls and sponge rubber to compress the wound and reappose the skin and subcutaneous insues to the sacrococcygeal fascia. This dressing is then reinforced with an adhesive tape dressing so applied as further to facilitate the reapposition of skin and fascia and to remove any tension from the sutures.
- 3 The scrupulous avoidance of needless sacrifice of uninvolved skin by removing in the initial incisions, only a thin strip of skin sufficient to include the osts of the cyst whether embryologic or artificial and any scar tissue present, resulting from previous incision and drainage or from more extensive procedures.

#### PREOPERATIVE PREPARATION

All patients, on admission are routinely given sits baths three times daily and instructed to cleanse the sacral area thoroughly with soap and water. Cevitamic acid roo milli grams daily is given by mouth. All patients

are given penicillin therapy from the day of admission—whether the condition of the cyt is quescent infected with or without dranting sinuses or abscessed Penicillin 15,000 units, is given inframuscularly every 3 hours.

When abscesses exist or inadequately draining anuses are present, preliminary morson and drainage are done with local 1 per cent procaine anesthesia. The incision for drainage is linear and made as close to the midline spossible to obviate later difficulties in securing intact skin flaps when complete excision of the cyst is done. Hair and other lose definition must be removed to assure cessation of infection and drainage (r a8). No patient is restyle for indical excision procedure until infection and induration have been thoroughly resolved by attraction and daily sterile dressings.

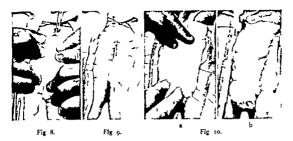

and only sterile cressings.

The night before surgery the sacrococycel area is carefully shaved. The patient receives two enemas one of warm water and one of glycrine and water. A third warm water enema is given in the morning a hour before operation. Morphine sulfate, ½ gran, so scopolamine ; are administered a hour profit operation. At the time of operation the operative field is again carefully scrubbed with sterile green soon and water.

# OPERATIVE PROCEDURE

The technique for this primary closure emphasizes the following points

- i Spinal anesthesia (4) is used.
- 2 Excision of but a narrow strip of skin is done in the midline often no wader than 14

mch to include the ostia of the cyst and scars from previous incision and drainage proce dures (Fig 1) The skin is cleanly and accur ately incised at right angles to facilitate meticulous approximation in the closure

3 Block dissection of the cyst is accomplished down to and exposing the sacrococcy geal fascia in its entirety (Fig 2). The skin edges are then undermined with the scalpel blade partially on the flat, the lateral fatty tissue divided and the subcutaneous tissue and a small amount of fat left attached to the flaps (Fig 3). The triangular strip of fatty tissue remaining on the gluteal fascia is then removed with scassors (Fig 4) thereby leaving the sacrococcygeal fascia and the gluteal fascia denuded bilaterally (Fig 5). Care is exercised throughout to avoid traumatizing the skin flaps or other tissues.

4 Thorough hemostasis is accomplished by the use of plain No coo catgut transfirmon liga tures, electrocoagulation wherever possible and frequent copious irrigations of the wound with hot sterile saline solution

5 Débridement of the wound is then done by carefully excising all loose tags of fat or fascia and floating out small clots and fat globules with further irrigations of hot saline solution

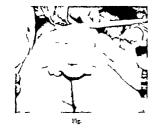

6 A sufficient number (usually 8 or 10) No 30 stainless steel through and through sutures are placed 1/2 inch apart through the skin under the gluteal fascia and under the sacrococcygeal fascia (Fig 6a and 6b) to be used to exert moderate pressure in closing dead space. Several may be required close

together at the distal end of the wound to assure closure of dead space here—especially if the skin incision required extension beyond the tip of the coccyx. The lowermost deep suture may pass through the bone itself if necessary to anchor the suture firmly in the depth of the wound.

7 The skin is then accurately reapposed with No 30 stainless steel wire vertical mat tress sutures (Fig. 7a and 7b)

8 After closure of the skin a thumb forceps is inserted through the upper end of the wound and any serum or blood is evacuated by exerting moderate pressure with gauze pads from below upward (Fig. 8). At this point following accurate reapposition of the wound the skin and its subcutaneous tissues will remain apposed to the sacrooccygeal fascia by atmospheric pressure alone restoring the intergluteal fold (Fig. 9). If however a slight tendency to suching occurs it does not indicate that tension is present and apposition will nonetheless be accomplished when the lateral wires are secured over the gauze dressing.

9 Loosely rolled gauze dressings are then carefully placed next to the suture line and over the wound to keep the tissues apposed to the sacrococcygeal fascia. A section of sponge rubber i by 2 by 4 inches is incorporated into the dressing and some manual pressure is maintained throughout. The through and through wires previously placed are then twisted over the whole dressing, beginning from below upward (Fig. 100 and 100). Care must be exercised to avoid tightening the

wires too much. The elasticity of the dressing itself maintains moderate pressure

- 10 Adhesive tape is then applied to the area in such a manner as further to relieve any tendency to tension on the sutures when the patient moves about in bed postopera tively (Fig. 11)
- 11 All sutures are removed on the 7th post operative day leaving no permanent foreign body in the wound (Fig. 12)

#### POSTOPERATIVE CARE

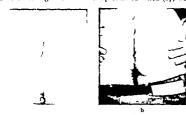

Following surgers, the patients are left at absolute bed rest on the abdomen or on either side for a period of 7 days. The penicilin in doses of 15 000 units every 3 hours intramus cularly is continued until the 8th postopera tive day. The cevitamic acid is likewise continued at 100 milligrams daily by mouth. A low residue high vitamin det is prescribed

and evacuation of the bowel is discouraged until after the sutures are removed. These patients get along surprisingly well and in only 2 instances, when durrhea was present, was evacuation necessary before 7 days. For tunately infection did not develop in either case. There was no appreciable postoperative pain and no necessary for morphile, though 1½ grains of nembutal was prescribed for nocturnal restlessness.

After the 7th day when the sutures have been removed, an enema is given and the patient is allowed toilet and shower privileges. They are cautioned against sitting or undue exertion for a few days to avoid putting stress on the recently headed wound

In treating the type of case described in Subgroup 3 that is, patients with recurrence who had been operated upon two or more times elsewhere and in whom there was an excessive amount of scarring and loss of six as evidenced by the flattening of the intergluteal folds, the primary closure described was not considered feasible nor was it intended for those large postoperative scar defects.

It will be agreed that the surgical problem encountered in such cases was something more than that of the treatment of pilonidal cyst alone. Even after the most conservative treatment at operation when the scar issue was excised these wounds gaped widely as might be expected so that some form of partial closure was necessar; to cover the defect if the prolonged healing time and wide delicate scars associated with healing by secondary intention (27) were to be avoided

The preoperative care and the operative procedure followed were identical with those described for the primary closure operation except that reapposition of the lateral skin flaps after excision of the scar tissue and granula tion tissue pockets was not possible nor con templated.

Accordingly the lateral skin flaps were freed and an adaptation of the horizontal mat treas suture suggested by Captain Harry R Huston M C USNR. Chief of Surgical Services at this hospital was used, effecting the partial closure of the defects by the expedient of securing the skin edges to the sacro-cocygeal fascia. This was done by the use of 4 to 6 horizontal, figure of eight, No 30 stain less steel wire mattress sutures that included the skin edges and the sacro-cocygeal fascia.

Sections of annall gauge rubber tubing were threaded on the wire sutures where they per forated the skin edges. The skin was then drawn down to the sacrococcygeal fascia with as little tension as possible and a greater or lesser gap left between the skin edges according to the amount of skin available to cover the defect. In 6 of these cases, the skin could be brought together with only a very narrow 1/2 inch defect. Accurate reapposition of the skin edges was not possible with this method, nor was it sought, because of the drainage required after excision of these scar tissue caybes.

The sutures were removed on the 7th post operative day by which time some pressure necrosis had occurred under the rubber of each suture. The skin remained attached to the fascia, however, and the center of the wounds healed by granulation tissue. These patients were kept at bed rest. Penicillin therapy 15 000 units every 3 hours, was continued for 10 to 12 days after operation The wounds were irrigated daily with azochloramide solu tion 1 5000 and probed daily with a sterile cotton applicator to break down pocketing A small dressing was then inserted and satur ated with a solution containing 33 milligrams of tyrothricin per 100 cubic centimeters of sterile distilled water

# REVIEW OF CASES

Subgroup 1 In the 66 patients (Subgroup 1) who had not been previously operated upon

20 were free of gross infection at the time of admission although all patients gave a history of previous exacerbations of swelling and ten derness over the cyst area. In 46 cases infec tion was present upon admission. Seventeen of these 46 patients had abscesses which required preliminary incision and drainage prior to operation for radical excision. In 15 other cases of infection acute inflammation was present on admission but there was adequate dramage through the embryologic ostra The inflammation subsided after the patient received hot sitz baths and penicillin therapy In the remaining 14 cases infection was present as evidenced by purulent secretion expressable from the ostia but there was no surrounding inflammation or induration. In these latter cases the infection also responded to sitz baths and penicillin therapy

Incision and drainage of the abscesses were carried out with t per cent procaine solution local anesthesia. An average of 4 hospital days elapsed before radical operation was per

formed in these cases.

As might be expected the locations of the secondary ostia and many of the scars from previous incision and drainage procedures were not conveniently located in the midline Many of the skin incisions later made at oper ation for radical removal were necessarily somewhat curved or irregular in shape in order to remove both scars and sinus openings in the sections of skin removed. The narrow strip of thin skin in the very center of the intergluteal fold was always included in the excision however because it is here that the embryologic ostia are situated In several instances the secondary ostia of these cysts were located an inch and a half or more to either side of the midline and directly lateral to embryologic ostin in the intergluteal fold Vertical curved incisions that would dreum vent both of these openings would necessarily include an excessive amount of normal skin In such cases, the usual strip of skin was removed in the midline and small horizontal elliptical incisions were made on either side of the scarred secondary ostia. These openings were thus buttonholed the ostia with the small elliptical area of akin attached being removed with the cyst as it was dissected en Ыос

In 4 instances sinuses extended to the perianal area where the tracts were palpable in the fat of the ischiorectal fossa. One sinus tract traversed the right ischioanal space about 2 centimeters lateral to the anal verge and opened in the perineum to the right of the urethra. There was one inverted 1 shaped sumus tract, the two limbs of which flanked the anus where an ostium was present overlying each ischiorectal fossa. The tracts in all cases were readily palpable.

In the differential diagnosis from fistula in ano (2 12 15) the tracts were palpable and found not to curve toward the anal canal but were traced directly to the cysts. Probes were readily introduced to trace the course of the tracts. Careful proctocopic examinations were done and the crypts were explored with a crypt hook for possible primary ostia of fistula in an

At operation these sinus tracts were incised over a grooved director and traced to the cyst. They were then completely excessed and the wounds closed as a continuation of the main cyst wound. The deep were sutures traversed the depths of the wounds in the fat of the isotroical fosser. The skin was closed in the usual manner as a continuation of the main cyst wound and the tension sutures tied over rolled gauge dressings.

In 60 of these cases the wounds were cleanly healed on the 7th postoperative day without pocketing hematoma, or other complication. Failure in the remaining 6 cases occurred as follows Three patients developed some pressure necrosis attendant upon the application of excessive pressure when the wires over the dressing were tightened. These patients complained of pain of a throbbing character which is indicative of this mistake. Areas of pressure necrosis 2/2 centimeters in diameter occurred on each side of the wounds where the compression sutures entered the skin. These required 15 17 and 18 days to heal. In 1 case a hematoma developed beneath the scar (2 22) making it necessary to open the overlying skin In this case healing was complete in 30 days. In 2 cases frank abscesses beneath the skin developed which required opening of the wounds These were probed with cotton applicators to break down pocketing arrigated with sterile saline solution and packed with small gauze dressings containing a solution of tyrothricin, 33 milligrams per 100 cube centimeters of sterile distilled water. The intransacular pencillin was continued in all of these cases for 7 additional days in the first 3 and 15 days in the other 3. The tyrothrian solution was added to the dressing every 3 hours and dressings changed daily. In the abscessed patients, the wounds were not allowed to gape but the skin edges were kept toward the midline by the use of large addesive tape bridges. The dressings were applied under the bridges. The average healing time in these 66 cases was 8.7 days.

Subgross 2 The 21 patients with recurrent pilonidal cyst comprising Subgroup 2 had been operated upon elsewhere prior to their admission and infection was present in all cases though there were no abscesses. Thirteen of them had been operated upon two or more times (in 2 instances, 3 operations) but it was impossible to determine what method or methods had been used. The common denormator in this subgroup that made them appear to be amenable to primary closure was the presence of seemingly adequate healthy skin which had not been unduly sacrificed in the previous surfical procedures.

At operation in 3 of the patients who had been operated upon once grously appearing cyalic tissue was present. All of the remaining cases were found to be recurrent because faulty healing and the presence of chronic granulation tissue pockets (22 28) and infected scar tissue.

All of these patients were treated as in group 1 by primary closure after radical excision of scar tissue and granulation tissue pockets. In 15 of these 21 cases healing per primare occurred in 7 days. There were 6 failures, the long est healing time of which was 40 days and the shortest 20 days. In 1 of these 6 cases then had been severe infection upon admission considerable pocketing and scarting and failuring ostita 2 centimeters from the right of the midtine. In this case dead space was not completely dealt with at operation or the lateral skin flaps were too long. There was pocketing under the skin when the sutures were removed and bloody purulent materal

was present. The wound was partially laid open and redressed daily. A sterile dressing was placed in the wound and saturated with tyrothricin solution 33 milligrams per 100 cubic centimeters of distilled water tyrothricin was added to the dressing every a hours. Large adhesive tape bridges prevented the wound from gaping and the dressings were applied under the bridges. In 2 cases small hematomas developed which were evacuated on the 7th day when the statches were removed Fortunately, they occupied only a portion of the wound and the recently healed incisions overlying the hematomas were only partially separated. Here again tyrothricin was used locally in the manner described. In the remaining 3 patients although firm healing took place otherwise small unhealed areas of granulations developed where the skin was reapposed Until these areas were thoroughly dry the wounds could not be classified as bealed

In these cases Carnoy a solution was applied and curettement of the excess granulations carried out after which a small pledget of tyrothricin soaked cotton or gauze was applied and secured by adhesive tape. Covering the wet dressings with waxed paper prevented rapid evaporation in the dressing. The first 3 failures were kept on intramuscular penicillin for 10 additional days making a total of 20 days per case. The latter 3 patients did not require additional penicillin therapy. The average healing time in this subgroup was 12 6 days.

Subgroup 3 These 13 patents admitted with recurrences of pilonoidal cyst had all been operated upon elsewhere two or more times. Upon admission each of these patients was found to have persistent sinuses marked scarring and an excessive amount of skin loss over the sacrococygeal area from previous operative procedures

At operation the sinus tracts were found to be granulation tissue pockets due to faulty healing rather than to residual cystic tissue. In appraising these patients for further surgery primary closure was not considered feasible. The preoperative care and the operative procedure used were for the most part identical with that described for primary closure including removal of all scar tissue and the lateral triangles of fatty tissue overlying the glutea. A partial closure was then done by the use of horizontal mattress sutures through the skin and sacrococcygeal fascia. The su tures were removed on the 7th postoperative day and the wounds were irrigated with 1/5000 azochloramide solution Dauly dressings were done and frequent explorations of the wounds were made with sterile cotton applicators to prevent bridging and pocketing. Slowly heal ing granulations were treated with Carnoy's solution and curettement. Five of the later patients were treated locally by dressings saturated in tyrothricin solution 33 milh grams per 100 cubic centimeters of sterile distilled water Penicillin in 15 000 unit doses. every 3 hours intramuscularly was given without interruption for an average of 18 days The shortest period of time of healing and of penicillin therapy was 12 days (5 cases) and the longest period was 45 days (2 cases) The average healing time was 26 5 days. This is not the method of choice for the treatment of patients with pilonidal cysts not previously operated upon but it is a necessary and valuable expedient in some cases in the handling of some recurrences in which primary closure cannot be accomplished

### DISCUSSION AND CONCLUSIONS

David, Gage Kooistra, and others have long advocated primary closure in dealing with pilonidal cyst before the advent of penicilin and tyrothricin and have presented substantiating evidence favoring the rapid healing and smaller scars attendant upon this method of treatment. Bream pointed out that such scars are more resistant to trauma

Tendler Kleckner MacFee Theis and Rusher and others are agreed that complete excision is easential for cure and that open pack methods of treatment result in prolonged healing and wide delicate scars. That primary skin closures prevent subcutaneous drainage and cause subcutaneous hematomas or serum collections which become infected and result in sinus formation (2, 22, 28) was not borne out by this series of cases. These complications are largely obvisted in the described technique by transfixion ligature of all bleed

ing points penicillin therapy and the use of the through-and through wires for the compression dressing. It is well to point out, however that in cases in which there is failure of primary bealing it is most likely to be due to a hematoma which is readily apparent and palpable on the 7th postoperative day when the sutures are removed.

Magrath believes that the present appellation of pilonidal or sacrococygeal cyst or sinus is unsatisfactory and that the present statistical method of reporting end results of operative procedures is misleading. He fur ther states that under the present system of all inclusiveness, one series of cases may present such extraordinary results that a surgeon may attempt the same type of operation with an entirely different type of involvement and thereby have discourszing results.

Accordingly the author has herein reported a consecutive series of cases and has attempted to lay down the criteria used in a given case in electing to use a technique of primary closure or a method of partial closure followed by tyrothrich dressings. These same criteria and techniques have been used by the writer in operating upon an additional 138 consecutive patients for pilonidal cyst since the completion of the series herein reported and have been found to be applicable in treating pilonidal disease irrespective of the extentof involvement encountered

Fourteen months have elapsed anner the beginning of this series, during which time all of these roo patients have been followed care fully by physical examinations or through periodic questionnaires, stressing pain, soreness, drainage swelling or any disability

The results to date are as follows there were 5 patients with recurrences in this series—3 of whom have been reoperated upon else where and 2 who will undoubtedly require further surgery. In checking back into the operative records and case histories of these recurrences, it was found that 4 of them were in the Subgroup 3 and 1 was in the Subgroup 2 All 5 patients had been operated upon prior to the operation done by the author. In the early part of this series certain significant errors and omissions of technique and medication were made which may well account for

these failures. It was found that in 2 of these early Subgroup 3 cases in which the previous operative scars had been seemingly adequately excised and the skin undermined and sermed to the fascia in the usual manner the throughand through sutures had been omitted and tyrothricin had not been available in the post operative treatment. The other 2 recurrences in group 3 were it is believed, the result of faulty surgical judgment. That is, in these i early cases, the lower third only, of the previous operative scars had been excised as it was in this area alone that recurrence had occurred and it seemed to be an adequate procedure at the time. The edges of the wounds were secured to the sacrococryxed fascia after the skin was undermined in the usual manner One patient had received local tyrothricin after operation and I had not. In any event, this pseudoconservatism in exching only a portion of such a recurrent cyst scar is to be condemned. The other recurrence was in Subgroup 2 The patient had been operated upon twice before and the author made an ill-advised effort to do a primary closure. This failed on the 7th postoperative day as a result of hematoma and the wound required opening and packing with azochloramide 1/5000 dressings. Here again tyrothricin had not yet been made available

It has been observed and repeatedly recorded (21 27) that recurrences are due occasionally to inadequate existion of the sinus but usually to infected granulation usually independent of the sinus but usually to infected granulation usuallined pockets in the depth of the wound. It would seem from this fact and from a study of these recurrences, that saide from the errors of omission in failing to obliterate dead space, the continuous use of tyrotinean solution topically is an indispensable factor in combating infection in these open wounds and in thereby promoting sound healing

Recurrence has not taken place in any of the 75 patients in whom primary cosume was accomplished nor in those patients in whom partial closure with through-and-through wires and tyrothricin dressings was used although all of these men returned to active and oftentimes, to attenuous duty in the may and at this time to various active pursuits in cryllan life. Incisions done for drainage of pilondal cysts preliminary to radical excision or even as a palliative measure for abscess should be made in a position giving due thought to the preservation of the skin for closure in later operation for total removal namely in the midline in the intergluteal fold whenever possible. In this manner, the artificial production of eccentrically situated ostia and sinuses can be largely circumvented and later operation symplified.

Surprisingly enough tender or painful scars have not been an outstanding sequela of this method of treatment although the fat in the interviuteal fold was almost completely ex cised and the wounds closed as described. In the author's experience, tender postoperative scars frequently result from other factors than the lack of a fat pad over the sacrum Tender or painful scars often occur when the skin and scar over the intergluteal fold are under ten sion as in the cases following elliptical incisions for block dissection and primary closure Pain is frequently complained of in the thick broad, adherent scars resulting from block dissection and open pack methods of treat ment or in cases in which deep permanent sutures have been used. Fourteen of the 75 patients treated by primary closure reported various degrees of tightness in the operative scar upon benching over as to tie a shoe lace or discomfiture upon prolonged sitting follow ing a train ride but in no case was it an especially noteworthy complaint and these patients were highly satisfied with the results obtained This tightness was noticeable to more or less extent depending upon the type of work done by the individual and occurred periodically for an average of 8 weeks after operation The other 61 patients in this category reported complete freedom from any local postoperative tenderness or discomfiture after initial healing had taken place. As might be expected more persistently tender scars occurred in the Subgroup 3 patients in whom the wounds had been of necessity left par tially open and healed in by granulation tissue Even here however there were individual variations in tenderness reported that were no more or less than would be expected follow ing any secondarily healed wound in this area.

It is believed that the method of treatment herein presented largely overcomes the causes of recurrence by the use respectively of radical excisions to obviate sinus remnants and a maximum of penicillin therapy plus oblitera tion of dead space to prevent granulation tissue lined pockets

In the author's opinion primary closure is the method of choice in the treatment of pilonidal cyst. The procedure is both practicable and desirable in the vast majority of cases and is adaptable even to some cases of recurrence following other procedures. It eliminates the protracted postoperative treatment and disability attendant upon open methods and circumvents the open wound and attendant infection which is such an important factor in the production of the infected granulation insue lined sinuses of recurrences. The method results in the restoration of a normal intergluteal contour with a minimum of scar tissue that is resistent to training.

#### SUMMARY

I A series of 100 consecutive patients oper ated upon for pilonidal cyst has been analyzed

2 Å technique that stresses sparing of the skin radical excision of all cystic tissue and adjacent fat tissue routine use of penicillin therapy and a type of primary closure that eliminates dead space was used for all patients who had not been previously operated upon (66 cases) primary healing being obtained in 90 9 per cent

3 The same technique was used in recur rences in which the skin had not been unduly sacrificed by previous surgical procedures (21 cases) primary healing being obtained in 71 per cent

4 Partial closure was used in treating recurrences in which the skin had been too widely sacrificed by previous operative procedures to permit primary closure (13 cases) average healing time in these was 26 5 days

# THE LATERAL ABERRANT THYROID

FRANK H LAHEY M.D., F.A.C.S. and BERNARD J FICARRA M.D. Boston Massachusetts

THE subject of the diagnosis and han dling of lateral aberrant thyroid tissue is of importance for many reasons The existence of tumors arising in such tissue is apparently often not appreciated. They are all potentially malignant. Patients with such tumors respond well when treated by radical operation and intensive radiation. Aberrant thyroid tissue occurs in different types of tumors large and discrete as multiple gland like masses and occurring at the same time as they not infrequently do in the thyroid gland and along the internal jugular veins the tumor in this gland is wrongly con sidered the primary focus of malignant disease, the aberrant thyroid masses along the internal jugular veins metastases and the out come considered honeless.

In the course of embryonic development thyroid tissue which persusts outside of the thyroid gland proper is termed aberrant thy roid tissue. Aberrant thyroid tissue may be of lateral, median or ectopic origin. Lateral aberrant thyroid tissue finds its origin in the ultimobranchial bodies. At the beginning of the seventh embryonic week each ultimobran chial body united with the adjacent fourth parathyroid is set free from the pharynx. During this time growth of the thyroid brings its two lobes into contact with the ultimobran chial bodies. Each of the latter then loses its cavity and becomes incorporated into the thy rold gland. Occasionally the ultimobranchial bodies undergo conversion into thyroid tissue. This conversion is attributed to the dominat ing influence of a thyroid environment on a plastic, implanted tissue. To this degree the ultimobranchial bodies are lateral aberrant thyroid primordia (1) (Fig. 1)

#### INCIDENCE

The presence of lateral aberrant thyroid tu mors is not a common clinical entity. A study at this clinic revealed 30 patients with lateral aberrant thyroid tumors encountered prior to January 1939 (2) Since that date 17 addi tional patients have been treated up to and in cluding June 1945. During this period 25 000 patients were treated for various types of goi ter. Thus approximately 1 patient with lat eral aberrant thyroid was seen for every 500 patients with goiter.

An analysis of the 30 cases seen prior to January 1939 indicates that these tumors may occur in patients at any age but usually under 40 years. They occurred five times more frequently in women than in men. Histopathologic diagnosis in all cases was papillarly cystadenoma showing little differentiation into adult thyroid structure. All were considered either potentially or definitely malignant. As such, the patients were treated by radical operation followed by radiation therapy.

The 17 most recent cases studied at the clinic since January 1939 are presented in Table I

#### CLINICAL PICTURE

Tumors arising in lateral aberrant thyroid tissue produce no characteristic symptoms. The presence of a swelling in the neck is noticed by the patient or found by the examining physician. Most commonly a history is given of a swelling symptomless at onset, which gradually increases in size over a period of months or years. The growth is not only gradual but may not alter its size shape or consistency over a period of years. Occasionally after a long period of no growth a recent rapid increase in size may be noted and cause the patient to seek advice.

These tumors are usually multiple producing movable gland like meases which are located along the neck in front of the sternomastond beside the internal jugular vein (Fig. 2b). At times a long chain of nodules gland like in character can be palpated from the mastoid process and at times below the clavicle along the sternomastoid muscle on one or both sides (Fig. 2a). Occasionally a single deep good sized tumor of the neck, firm in character not unlike a carotid body tumor will prove to be a single lateral aberrant thyroid (Fig. 2c).

#### DIFFERENTIAL DIAGNOSIS

The chincal diagnosis of tumors originating in lateral aberrant thyroid tissue is often not made unless one recalls that any laterally located mass may be a lateral aberrant thyroid tumor. In our series before 1939, a correct diagnosis was made preoperatively in 16 per cent of the cases with a tentative diagnosis of lateral aberrant thyroid tumor in an additional 33 per cent. As our knowledge and experience with these tumors have increased our ability to distinguish them preoperatively has like wise increased. In our second series of 17 cases the correct diagnosis was made preoperatively in 80 per cent of these patients.

Aberrant thyroid tumors must be distinguished from all the simple tumors of the neck. By dividing these tumors into median line tumors and lateral neck tumors a simple and practical classification is made available (Fig. 3).

Median line tumors are for practical pur posses almost all limited to the thyroid gland They are the tumors that are limited to the descent of the thyroid. These are the undescended thyroids from their point of origin at the base of the tongue the sublingual thyroids the thyroglossal cysts the pyramidal lobes and the adenomas in the isthmus. The single lateral tumors and sinuses of the neckare the branchial sinuses branchial cysts carot id body tumors and neurofitromas. The mul-

Γig 1

tiple tumors are the aberrant thyroids tubercu lous glands inflammatory nonspecific glands the various other inflammatory types and metastatic and nonmetastatic neoplastic in vasions of glands. In this group of multiple tumors occurs the greatest difficulty in distinguishing tumors of lateral aberrant thyroid origin. Table II will assist in the differential diagnosis of these tumors.

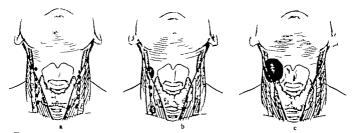

Fig. 2. a, This illustration shows the occurrence of a chain of giand-like bodies often on both adea, in front of the sternomastoid muscle healds the internal jugular vein in lateral aberrant thyroid. b, Multiple gland like bodies,

irregular in size, of lateral aberrant thyroid, occurring lat erally c. The occasional occurrence of a single, discrete good-sized nodule, often not unlike a carotid body tumor is demonstrated

#### PATHOLOGY

Macroscopic inspection of lateral aberrant thyroid tumors frequently reveals a bluishblack discoloration of the tumor tissue. This color results from blood pigment which weeps from the papilliterous elements of the tumor

The histologic appearance of these tumors is that of a papillary cystadenomatous structure (Fig. 4). Adult thyroid elements are not visualized. This makes it difficult to identify the tissue as of thyroid origin. The macroscopic appearance of this papilliferous tissue is so characteristic and constant, however that whenever a tumor is removed from the

CLASSIFICATION OF SIMPLE NECK TUMORS

lateral region of the neck and is diagnosed at papillary cystadenoma, it is in all probability a lateral aberrant thyroid and is actually or potentially malignant.

Invasive tendencies are found in many of our cases were definitely adenocarcinoma both in cell structure and in invasive charactristics (Fig. 5). In our classification papilary cystadenoma malignant is a little more differentiated and a little less malignant than the papillary adenocarcinoma. Histologically the tumor is predominantly papillary adenocarcinoma with blood vessel invasion.

The problem often arms as to whether or wo these tumors are metastatic glands with the thyroid gland as the primary site of the growth. Several of our patients have shown unlisteral unvolvement of a thyroid lobe with a nodule of papilliferous tissue within the thyroid gland itself. In the majority of instances, however lateral aberrant thyroid nodules have occured with an entirely normal and unnvolved with an entirely normal and unnvolved thyroid gland. When the thyroid gland has been involved, equally good results have followed bemuthyroidectomy including the nodule plus the removal of the lateral nodules and radiation as have followed in the cases in which so nodule was present in the thyroid. Papillary

Fig. 4. The typical papillary cystadenomatous structure of lateral aberrant thyroid tissue is illustrated.

cystadenomatous structures along and behind the sternomastoid muscle as well as those within the thyroid lobe itself can be explained on embryologic grounds without spread or me tastasis in either direction. The lateral aber rant cell masses fuse very early in the embryo with the thyroid of median origin. Since the tumors occur anywhere laterally in the neck or in the thyroid it is probable that the papil liferous aberrant thyroid nodule which also occurs within the thyroid lobe represents another lateral aberrant nodule fused with the thyroid which has failed to atrophy

#### TREATMENT

When multiple tumors of the neck are present an early biopsy to determine the nature of the leason is important in order to under take proper and adequate treatment, particularly when the microscopic report is papillary adenocarcinoma. A diagnosis of lateral aber rant thyroid nodules demands radical surgical

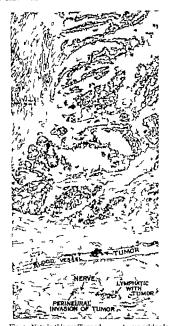

Fig 5. Note in this papillary adenocarcinoma arising in lateral aberrant thyroid tissue all types of invasion blood vessel invasion, penneural invasion, and lymphatic invasion.

treatment followed by intensive postoperative radiation therapy

When a discrete nodule is found without in volvement of the thyroid lobe and without other lateral aberrant thyroid nodules, com plete removal may be sufficient. When several nodules are encountered dissection of the neck on that side is indicated. In the presence of invasion characteristics and the diagnosis of papillary adenocarcinoma, radical neck dissection on the side involved should be performed. This dissection includes removal of the sternomastoid muscle internal jugular.

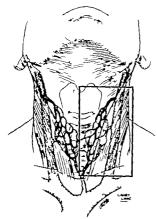

Fig 6. This illustration diagrammatically shows the block of time t be removed in potients with aberrant thyroid times containing papillary adenocareinoma.

Not that this block includes the sternomastoid, the internal jupils th all of its tributaries entering the thyroid, all of the lymphatic nodes and all of the thyroid tissue on the side involved.

vein all lymph nodes and total hemithy rodectomy on that side (Fig. 6)

Postoperative radiation therapy has been employed in all cases in which any criteria of malignancy were demonstrated. A total of 6000 r is applied to the tumor bed over a 22 day period. During the period of treatment serum cholesterol levels are taken. If this level rises to 300 milligrams or more small doses of thyroid extract are administered.

#### FOLLOW UP STIMUS

In our series of cases prior to 1939 our follow up studies show the following. Twentley one of our patients have been followed from 5 to 15 years. Fourteen patients have had no recurrence. During this period 3 have died of other proved causes. Three had recurrence were reoperated upon and are now well. Two are living with recurrence. One patient has had repeated pathologic fractures of the right humerus and another has metastases in boh lungs. One patient died of recurrent miligenant disease of lateral aberrant thyroid organ. Of the other 9 patients, 6 had no recurrence after 4 years. One had a recurrence, was to operated upon and is now well. One patient is living with recurrence. The last patient died of metastases from carcinoma of the hierant (2).

Our second group of 17 cases since 1939 encompasses a follow up period of only 6 year. In 140 these patients recurrence was recorded, in 1 case after 4 years followed by respectance of lymph node metastases 1 year later Reoperation on two different occasions revealed additional tumor. This patient is now well. Three cases are too recent to discuss.

The results of our follow up survey in the entire group confirm the pathologat's beift that tumors of lateral aberrant thyroid orgus are of low malignancy. Adequate radical surgical treatment followed by radiation therapy offers a very favorable prognosis.

#### SUMMARY AND CONCLUSIONS

Tumors of lateral aberrant thyroid origin are discussed. These tumors arise from the ultimobranchial body as a result of departure from normal embryologic development.

Forty-seven instances of these tumors were encountered at the Labey Clinic up to July i 1945. During this same period 25,000 patients were treated for various types of gotter. Thus, one tumor of this type is seen in approximately every 500 gotter patients.

These tumors may occur in patients of any age but usually in those under 40 years. They are more frequent in women than in men.

Clinical diagnosis can usually be made. The leason must be distinguished from the ample neck tumors branchad cysts, carotid body tumors, and neurofibromas. In particular differentiation must be made from tuberubosis, lymphosarcoma, Hodgkin a disease mammatory glands, and metastatic caremona Diagnostis is confirmed by bloppy

The characteristic pathologic picture is a papillary cystadenomatous structure showing little if any differentiation into adult thyroid structure All these tumors must be considered as actually or potentially malignant

Radical neck dissection followed by deep ra diation therapy is the most satisfactory course of treatment. This lesion is of low malignancy and is radiosensitive.

The operative mortality in 47 cases was nil Follow up studies of 30 patients prior to 1939 cover a period of 5 to 15 years. Twenty one of these patients showed no recurrence 4 had recurrence were reoperated upon and have remained well Four died of other causes. One patient died of recurrent malignant disease of lateral aberrant thyroid origin

Follow up study of our most recent 17 cases encompasses the past 6 years. One patient

had a recurrence was reoperated upon twice and has remained well. Three cases are too recent to discuss.

In conclusion whenever a biopsy specimen is taken of a tumor from the lateral region of the neck and the report is papilliferous cyst adenoma or papillary adenocarcinoma in all probability it is a lateral aberrant thyroid Adequate surgical and radiation therapy will result in an ultimate favorable prognosis in the majority of cases

# URINARY INCONTINENCE DUE TO BILATERAL ECTOPIC URETERS

# I AURENCE & CREENE, M.D. and DEWARD OFFRRIS M.D. Rochester Minnesota

RINAR's incontinence due to an ectopic uncertaint of the rind common. In 1918 Eisendrath (1) reported a series of 155 cases of urcters with ectopic openings which he had collected from the literature. In most of the cases the condition was unisternal balateral ectopic ureters were infrequent.

The ectopic ureter is usually avocated with complete duplication of the pelvis and ureter. In most instances the opening of the ureter which leads from the upper agment of the duplicant kilney is ectopic. Rarely, the ureter from the lower agment is ectopic or an ectopic ureter may occur with a kilney which is not duplicated.

I rose the Section on Urology and the Division of Suggery M v. Clanc.

Fig. Extretory program. Duplication of the pelvia and califors of the left inducy is also well. Duplication of the right lodney is suggested by the small amount of medium visible in the proof node.

In cases of bilateral ureteral ectopia the orifices of the ectopic ureters are most frequently situated in the urethra or the vestibule of the vagua. Less frequently one or both ureters enter the prostate urethra, vas deferens, ejaculatory doct, uterus, or vagua.

The condition occurs with much greater for quency among women than among men and the outstanding symptom among women is stream incontinence. In practically all cases the incontinence is congenital diurnal and noctumal and associated with normal voldings. Among men incontinence is usually absent and the conduct is discovered following investigation to determine the source of infection of the urnary tract.

The dagnosis of bilateral ectopic ureten may be exceedingly difficult and, at times, can be only inferred, as in Case 2. If the symptoms suggest ectopic ureter the urethra, vestibule, and vigens must be carefully examined and a search made for the escape of urine from the ectopic order. The intravenous administration of indigocarmore is usually of little value because the function of the portion of kidney drained by the ectopic ureter is not sufficient to concentrate the dye in the urine. It may be possible to eathernore the ectopic uniterest and to secure recolorance as mick!

ureters and to secure pyelograms, as in Case I Excretory urography is valuable in the dist nosis of this condition (2) In most instances bilateral complete duplication of the renal pelver and ureters will be found. However those Kgments of the kidney drained by the ectopic areters (usually the upper) will be visualized family or not at all, because their function is insufficient to concentrate the contrast medium. In such mstances the diagnosis of bilateral complete doplecation must be inferred from the fact that the visualized pelves (usually the lower) appear to drain only the lower portion of each kidney Thus if by excretory prography and retrograde pyelography a diagnosis of bilateral complete displication of the pelvis and ureter is made and if but one ureteral orifice is situated at each extremity of the trigone, a diagnosas of bilateral ureteral ectoph can be made.

In instances in which the ectopic ureters empty into the urethra, the instillation of indigocarmine

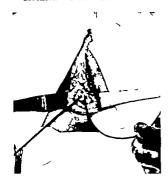

Fig.s The openings of the ectopic ure ters into the vestibule of the vagins.

into the bladder is of diagnostic value as in Case 2. The escape of urine, uncolored with indigocarmine, from the urethra after the dye has been instilled into the bladder is conclusive evidence of the presence of an ectopic ureteral orifice situated in the urethra.

Because of the infrequency of this condition the following 2 cases of bilateral ureteral ectopia are reported

#### REPORT OF CASES

CASE: A single woman, so years of age, stated that she had had urfary locontience since birth and that, as long as she could recall ber undertoltes had been wet. At no time had there been any diumal, seasonal or yearly warl ation at all times her perfocum was constantly and monot councily wet. As a child she had been exmined and treated by several physicians but to no avail. Drastic limitation of fluids and wolding every hour by the clock, during the day and night produced no change. Her parents evolved a schedule whereby the child would recrive as a reward a blue paper star for each day that the remained continent and a good star for each day that the remained continent and a good star for each werk, strews as he might, the unfortunate child never earned a blue star.

hemelt to a wet perfueum. As the maturett, however the found it necessary to change her residence to another state, chiefly because her friends complained of the urinous ode. Two years before coming to the clinic site again had sought medical and. Cystocopic examinatio, had been performed and she had been informed that her right tid ey was in fected and that the cut-off muccle was weak. A plattic procedure whereby the muscles of the urethra were tight ended had been carried out but without benefit.

She stated that she used three sanitary pads during the day and three during the night. She had no other urinary symptoms. She voided easily and painlessly three—four tunes daily and did not have nocturia.

The only pertinent finding n physical examination was inflammation and tenderness of the skin of the vulys and

thighs the urinous odor of these parts was evident. Routine laboratory studies, including urinalysts, yielded normal or negative results. The concentration of urea was 22 n illigrams per 100 cubic centimeters of blood

An exerctory urogram (Fig. 1) revealed complete duptil cation of the pelvis and calices of the left kidney, the visualization of the left ureter was not sufficient to dete more whether this ureter shows an duplicated. The pelvis and calices of the right kidney appeared to be normal a small amount of medium appeared to be present in the upper pole of the right kidney above the visualized pelvis and suggested the presence of duplication. The right ureter was not visualized sufficiently for accurate diagnosis.

Cystoscopy revealed the bladder to be normal one ureteral ordice was situated at either extremity of the trigone. Blisteral retrogated perlegrams outlined only the lower pelves of both kidneys and these appeared normal Specimens of urine which were collected from each kidney were negative microscopically and by means of Gram's

stain. Careful examination of the urethra failed to disclose an ectopic ureteral orifice. After the intravenous administration of indigocarmine diligent examination of the vestibule and considerable probing of various folds finally revealed two ectopic ureteral orifices (Fig. 2). The orifice of the ureter leading from the upper segment of the right kulney was stuated directly below the urethral onfice and a uretral catheter was passed with ease. The orifice of the uretre leading from the upper segment of the left kidney was situated below and starral to the urethral orifice a

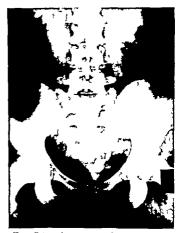

Fig 3 Retrograde ureterogram. The lower portion of the ureter from the upper segment of the left kidney is dilated and torthous. The upper segment of the right kid ney and its uret r are incompletely visualized.

Fig. 4. Bilateral retrograde pyelogram. Complete bl. lateral duplication with bilateral ectopic ureters is shown. Vasualization of the upper segment of the left kidney and its arter is poor because the cutheter could be inserted up the ureter for only—short distance.

ureteral exhibitor could be passed up this retter for only short distances and retrograd prelogram revealed marked dilatation and tortoodity of the lower third of the ectopic left oreter (Fig. 3). A retrograde prelogram of the upper segment of the right bidney disclosed: rudimentary periors and ureterectusis (Fig. 4). Examination of specimen of owns from this segment revealed pravits and bacillaria.

A diagnosis as made of bilateral, complete duplication of the pelves, calices and areters, ith the ordices of the ureters from both upper segments attented ectopically in the vestibule. Bilateral beminephrectomy was advised and carried out.

At the time of the first operation the right kidney was exposed and it was noted that the upper separant represented proximately one-third of the total renal mass. Two sets of abernat vessic started is not superior polatical properties of the started proximately and its urrer passed through the structured posteriorly and its urrer passed through the structured posteriorly and its urrer to the structure of the structure of the structure of the through the renal policie. The abernat vessels are sepanted and ligated separately and the upper sepont of the

kidney was encised.

Convalence was uneventful but urinary incontinence persisted. In spite of our reassurance, the patient as perturbed because it was her impression that the urinary teakage had not been reduced by half.

Two weeks after the first operation surgical exploration of the left kidney was performed. The operative findings

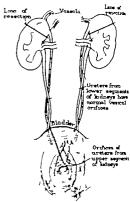

Fig 5. Diagrammatic scheme illustrating the fedor

and surgical procedures were essentially similar to those lists have been described for the right kidney. Left headreparectomy and partial ureterectomy were perferred with case.

After the second operation urisary incontinence curied cultiety. The patient was clared and stated, It's his new fif. An exercisory program made a cells after the second operation revealed powers if entire in to both resulting segments with no deformity of the pelves or calken (Fig. 0. Uritalysis's revealed normal findings and the construction of stress was so milligrams per 100 cubic certificities.

Case A girl, 9 years of age, was brought to the claim by her mother who stated that the child had been incutioned of urine since birth. More recently the patient and complained of burning in the region of the until at their respects the child appeared and behaved normally.

The pertinent finding on physical emainstation as the constant energy of small amount of urine from the crimmal meature. Urinalysis gave negative results. Routher studies of the blood and rocatgemograms of the thorize ere

An exercisory original suggested the possibility of cerplet displication of the pubric, calcer and meter of be the kidney. Although the upper segment could not be timelized, the position of the pelvis in relation to the set inseroutline of the kidney suggested this possibility. The pricince of similar condution of the right kidney as also suggested, but details were obscured (Fig. 2).

Cystoscopic examination ducioned the bladder to it normal, with one ureteral ordice situated t each extractly of the trigone. The internal resicul neck and uretral test appeared normal. A small opening as seen just. him the

Fig 6. Excretory urogram following bilateral heminephrectomy. Both lower segments are functioning normally visualization of the right kidney is incomplete.

external arethral meatus slightly to the left of the middine a catheter could be passed through this opening for only remlimeter. The remainder of the urethra appeared normal, indipocarmine was instilled into the bladder and observation of the urethra did not disclose the escape of any blue stained urine. However an escape of clear urine from the urethra was noted at regular intervals. This finding was considered as evidence that the uretral ordice corresponding to the upper asyment of the left kidney custerd the urethra. The possibility that an ordice from the upper segment of the right kidney was also situated in the urethra was considered. A recommendation of exploration of the left kidney was made in the event that incontinence per sisted after this procedure, a similar procedure on the right kidney was divised.

Emboration of the left kidney was carried out and complet duplied into a the period and ureter was noted. The upper balf of the kidney was found to consist of a hydronephrotic sac with little parenchyma remaining. The ureter leading from the upper segment was tortious and approximately a centimeter in diameter. The remainder of the kitney and the ureter from the lower segment appeared normal. Heminephrectomy, removing the upper segment, was carried out. The pathologist reported hydromephrosis, chronic prehomephritis and hydrometer- so per cent of the renal windstance had been destroyed.

The patient withstood the procedure well and convalescence was uneventful. Urinary inconti ence, however persasted. Excretory urography was repeated and the pel vis of the right kidney appeared normal but was seen to

Fig 7 Excretory urogram The size position, and configuration of the pelves suggest duplication of the pelves and calices.

occupy the lower half of the soft tissue outline of the right kidney. Considerable renal parenchyma appeared to exist above the visualized petvis and this finding strongly suggested the possibility of duplication of the petvis, calcies and ureter of the right kidney. The renaling lower segment of the left kidney was in t visualized satisfactorily but it appeared to be functioning normally.

Cystoscopy was repeated and the urethra was carefully examined, but a second ectopic ureteral orifice could not be found. Indipocarmine was again intilled into the bladder and again an escape of clear urine from the external urethral meatus was noted. This finding was considered as couch sive evidence of complete duplication of the right kidney with the ectopic opening of the ureter from the upper segment situated in the urethra.

Exploration of the right kidney was advised and carried out and complete duplication of the pelvis and ureter was found. The upper segment of the kidney was hydronephrot is and the corresponding ureter was extremely dilated. The lower segment of the kidney and its ureter appeared normal. Heminephrectomy, removing the upper segment, was carried out. The pathologist reported hydronephrosis, chronic pyckocphnitis, and hydroureter to per cent of the renal parenchyme was destroyed.

After the second operation the patient had pe feet un nary continence. Convalencemee was uneventful. An excre tory unogram revealed normal configuration of the lower segments of both kidneys and both appeared to be functioning normally T years after the last operation the patient informed us that sh had no urinary symptoms.

#### COMMENT

A correct diagnosis of ectopic ureter will enable the physician to achieve a brilliant cure by the proper surgical procedure—usually heminephrectomy. Female patients, miserable as a result of urinary incontinence can be restored to perfect continence and male patients can be relieved of

intractable urinary infection by proper dagnoss and sunjical treatment. If incontinence pensis among female patients after unilateral hemsephrectomy bilateral ureteral ectoba is suggested and further urologic investigation of the opposite kidney including exploration if necessary is adicated.

# STUDIES ON EXOPHTHALMOS PRODUCED BY THYROTROPIC HORMONE

III Further Study of Changes Induced in Fat by Thyrotropic Hormone (Tissue Reactions Associated With Exophthalmos)

RROWN M. DORYNS M.D. Rochester Minnesota

N a preceding publication (11) the reports of Paulson Aird Brock and Smelser which described the presence of round cells in tis L sues of animals given thyrotropic hormone were confirmed, Paulson (17 18) concluded that the reaction he described as Zenker's degeneration in muscle was most marked in the first few days of the administration of the hormone. I recently reported (11) that these new cellular components which appeared in tissue contained they droplets of fat and that the general reaction in fat depots was comparable to the reparative processes which occur in traumatized fat with fat necrosis. Fat was demonstrated by histologic techniques, in abnormal quantities not only in macrophages of connective tissue but in cardiac and skeletal musde fibers, in liver and kidney epithelium in epithelium of the ileum and in reticuloendothelial cells throughout the body

The nature of the reaction and the presence of fat droplets in macrophages and polymorphonu clear leucocytes of connective tissue led to the assumption that this was phagocytosis of fat and probably a form of rapid mobilization of fat Be cause fat seemed to be removed from depots and appeared elsewhere in seemingly abnormal quan tities, the supposition was that fat was being rapidly transported, perhaps via the blood stream Preliminary investigation on centrifuged blood revealed lipemic plasma and a marked increase of the thickness of the buffy coat suggesting leucocytosis. In previous studies with antuitrin T the fat depots did not readily recover their depleted fat and the fat that appeared elsewhere disappear ed rapidly This prompted the question whether fat was being metabolized more rapidly than usual Accordingly experiments were devised for the consideration of the following topics (1) the sequence of events in the histologic changes in duced in connective tissue and liver of guinea pigs

(2) a study of blood fats in such animals (3) a study of blood acetones in such animals and (4) changes that may take place in leucocytes in the circulating blood

#### METHODS

Inasmuch as the changes in the connective tissue of normal animals are as great as in thy roidectomized animals when thyrotropic hormone is administered normal intact animals have been used. The study was based on 14 animals receiv. ing antuitrin T 2 receiving purified thyrotropic factor 4 receiving specific metabolic principle and 8 normal control animals. Most interest centered about the animals receiving antuitrin T for it was this product which induced the most strik. ing reaction in tissues (11) Twelve of the animals which received a cubic centimeter of antuitrin T1 were killed in 31/2 to 24 hours after the single administration The remaining 2 received daily administration of antuitrin T for 2 and 3 days respectively before being killed. All animals were killed by exsanguination by means of an 18 gauge needle inserted through the thoracic wall into the

Coagulation of the blood so obtained was in hibited with sodium oxalate crystals. The blood was centrifuged slowly and only sufficiently to separate the cells from the linemic plasma plasma was dried, ground finely with sand and extracted three times (1 hour each) with a solvent composed of 50 per cent methyl alcohol and 50 per cent chloroform After evaporation of the solvent, the residue was dissolved in chloroform, filtered dried and weighed

The determination of blood acetone was done by the method of Crandall on whole blood

One cubic centimeter of antuitrin T was reported by the man f cturer to contain 3 Junkman -Schoeller units. This unit is defined as that amount of extract which when injected daily for 3 meet as that amount of either which when injected daily for a contract of the proper weighting on any of arms causes re-command the proper weighting on the stress cause of the collection of the contract of the collection and disappearance of collection to the collection of the col

Fig. Phasportonia of fat droplets by tissue macrophages and polymorphomolacule reluceytes in persuretime I depot of an I seet animal that had been given. Stalls continuents of animint I daily for two days. That is the picture seen early after the beginning of the diministration of animitin I Some of the sure macrophages suggest transformation atto dispolalasts (scarlet red and hematonylin, Xygo).

Determinations of fat in the plasma were made no 12 animals that received antuitin T. Eight of these animals were also studied for blood acctone Eight of the normal animals were studied for plasma fat and 5 of that number for blood acctone. Attention should be drawn to the fact that some of the antuitrin T that was used had been heated at a temperature of between 95 and 90 degrees C and 6H for hour. This heated product caused the usual changes in fat, in connective tissue, and organs just as the unheated product du (11).

The leucocytes from the circulating blood of these animals were studied. The cells were drawn up in a pipet from the buffy coat of the centraliged blood. The cells were smeared on a clean slide, fixed in formalia and stained with scarlet red and bemators in Such preparations were made in demikate and triplicate to avoid minimterpretation of artifacts. This procedure were ed as a means of judging the presence of fat droplets in the leucocytes of the blood stream.

The liver spleen, temporal muscle cardia muscle, lung thyroid, orbital contents and from several depots, including perfuretene, and lary cervical and testicular fat were all stables microscopically. These were fixed in ope cert formalla, sectioned on a freezing microtone and stained with scartier red and hematoxyim. The pathologic changes were graded on a base of its 4 (1 being the slightest discernible change and a being the most striking).

#### PERMITS.

As described previously (10) antutrin T cused the animals to become mactive muscularly seak and rough-coacted within a few bours. The same animals which were most profoundly affected had grossly cloudly blood plasma.

The development of kistologic changes. The abnormal appearance of fat in many different tesses was very evident in animals which had received a single administration only a few hours before. The liver muscle, kidney epithelial cells from several locations, the reticulo-endothelial cells of the lung and spleen and the polymorphonuclear levency ict, tissue macrophages and fibroblasts of connective tissue throughout the body were sites of aboutme! quantities of fat. The degree of change with regard both to the deposition of fat in abnormal quantities in various locations and to the development of the cellular reaction (with phagocytosis) in the connective tissue, became more evident at time elapsed following the injection of antuitrin T Two animals which received antuitrin T for only 31/2 hours before they were killed showed thanges which could be graded only I to 2 Two other animals killed in 5 hours showed changes which were graded 2 to 3 By 21 and 24 hours these changes were striking being graded 3 to 4. The tissue changes in these animals after a single in jection were compared with those that were found after numerous daily administrations of antuitra T (11) In animals treated for longer periods there were a decreasing amount of phagocytosis of fat and less fat in the liver keineys, muscle fibers and so forth. The new cellular elements appearing in the connective tissue remained strik ing but the fat droplets in such cells progressively diminished as longer periods of administration of antuitrin T were observed.

During the first few bours after the administration of antuitmn. The cellular reaction in connective lissues consisted of relatively, more poly morphonuclear leucocytes and large tisses merophages. After longer periods the polymorphorclear leucocytes had become relatively inferenced and fibroblasts and lymphocytes had increased.

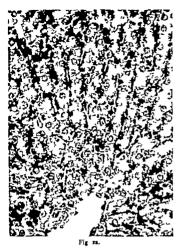

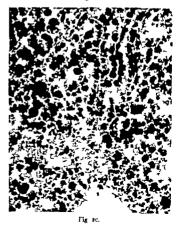

Fig. 2. Microscopic deposition of fat in the fiver of annuls receiving antuitrin T ( $\times 185$ ) a, Three and a half bours after administration of antuitrin T b, Five bours after c, Twenty-four bours after

The lymphocytes did not contain demonstrable fat droplets. Several things suggested a transforms tion from large mononuclear macrophages into fibroblasts. The incidence of fibroblasts seemed less very early but more common later. Cells could be found in all stages of transformation Fibroblasts contained fat droplets just as were found in the macrophages but the quantity of fat contained had become less prominent (Fig 1) These cellular changes were thus found to be a forerunner to the increase of connective tissue throughout the body seen particularly well in fat depots and described elsewhere (11) After 15 or more days of daily administration of antuitrin T the acute phase of the reaction had seemingly passed and in its place an increase of connective tissue was found

The sequence of changes induced in the liver. Special attention was directed toward a sequence of changes in the liver. It was known from former experiments (11) that antultin T caused the appearance of fat in the liver. In 334 hours very mute droplets of fat could be seen in the margin.

of the hepatic cells bordering the blood sinusoids. In 5 hours the fat droplets were larger and more numerous but still occupied that portion of the hepatic cells bordering the blood sinusoids. The fat was somewhat more abundant in the periportal region of each liver lobule than in other regions. Finally in 24 hours the hepatic cells were almost completely filled with fat droplets (Fig. 3) These changes were all induced by a single injection of antuitrin T This progressive accumulation of fat entering hepatic cells next to the blood sinusoids, adequately supports the hypothesis that fat is transported to the liver via the blood stream. An increased presence of fat in the periportal region of the lobule contributes additional support.

Changes induced in the thyroid epithelium. The epithelium of the thyroid gland contained many tiny fat droplets in the cytoplasm of the cell 24 hours after administration of a single large dose of antuntrin T The fat droplets were most numer ous toward the base of the cell Such droplets were not demonstrable in the thyroid cells of normal animals. Although this observation was made rather consistently the relationship of these fat droplets to the developing hyperplastic state in the cells is not understood (Fig 3)

Changes induced in the harderian gland. The harderian gland, which lies within the orbit inside the periorbita, is a ceruminous gland. Its waxlike contents stain deeply with scarlet red. After the administration of antuitrin T the normal waxlike contents of the cells of this gland were reduced in some animals in which considerable alteration of fat was observed elsewhere in the body. How ever the fact that the fat changes in this gland in some animals were not consistent with other

fat changes casts some doubt on this relationship Results of plasma fat determinate us The presence of lipemic plasma in many of these animals which were treated with antuitin T has been mentioned Ouantitative determinations of plasma lipoids reveal considerable elevation of total ippoids after administration of antuitrin T. The plasma lipoids ranged from 140 milligrams to 400 milligrams per 100 cubic centimeters of pleasan in the 8 normal animals. Animals killed 33/2 to 5 bours after administration of a single dose of antuitrin T showed no appreciable rise of plasma lipoids when compared with normal animals. On the other hand after 21 to 24 hours plasma lipoids were found to be as high as 1,050 milligrams per 100 cubic centimeters of plasma. Only 2 of 8 such animals were found to have plasma lipoid levels which were within the range of the normal animals

Results | blood acetone determinations Blood acctone was calculated in terms of beta-oxybu

twric acid. Blood acetone of 5 of the 8 normal animals was determined. The range in these animals was 1.0 milligram to 3.3 milligrams per 100 cubic centume(era of whole blood. Seven of the eight animals which were killed in at 10 a hours after a single injection of antuitin T rece studied for blood acetone. In this group of asi mals the range was 7-4 milligrams to 11-9 milgrams per 100 cubic centimeters of whole blood Although the method of determining blood act tone may be open to some criticism, the results suggest a change in these animals that have re celved antuitrin T

Results in animals treated with so called purific thyrotropic factor Two animals received I cubic centimeter of so called purified thyrotropic lactor containing 5 Rowlands-Parkes units and were killed in twenty hours. The pleasas fat was not elevated in one (280 mgm per 100 cc. of planes) and only very alightly elevated in another (4m mgm per 100 c.c.) Blood acetone in these and mals was 0.4 milligrams and 8.3 milligrams pe 100 c c. of blood respectively

Animals receiving the specific metabolic pracaple showed no appreciable change in plasms lati

Cellular changes induced in blood by thyratrops kormone This report is based on the follower animals 5 received antuiting T 3 received a crude thyrotropic preparation 3 received specific metabolic principle and 4 were normal animah Most interest centers about the animals which re ceived antuitrin T Not only was there an increase in the thickness of the buffy coat of the blood of animals treated with antuitrin T but the polymorphonuckar cells were in great excess. A differential leucocyte count on the animals gives antuitrin T revealed that 82 to 94 per cent of the cells were polymorphonuclear leucocytes in 4 of the 5 animals. This is in marked contrast to the normal animals, which had 5 to 14 per cent of polymorphonuclear leucocytes in 3 of 4 animah In the fourth animal the proportion was so per cent Because of the striking increase of the thick ness of the buffy coat in the blood of animals treated with antuitrin T it may be assumed that the reversal of the ratio represented a polymor phonuclear leucocytosus.

A crude thyrotropic preparation caused a poly morphonuclear leucocyte response in the circumstance in the circum lating blood similar to that produced by antifirm The specific metabolic principle camed a similar response in 2 of the 3 animals.

"One Rowinsde-Parker tax is he amount both her injected dely for f day take too green tensuing greens just Rull cases the thyseol double its week, at these weight of the publication ray."

Studies on Exophikalmos Produced by Thyrotropic Hormone III Further Study of Changes Induced in Fat Thyrotropic Hormons (Tissus Reactions Associated with Exophthalmos) —Brown M. Dobyns

The fat stained smear of the cells comprising the buffy coat showed fine droplets of fat in the poly morphonuclear cells. These fat droplets were very abundant and large in animals treated with antui trin T but they were relatively small and much less frequent in the cells of the blood of normal animals or animals that had been treated with specific metabolic principle. Animals that had been treated with the crude thyrotropic prepara tion showed some increase of fat in polymorphonuclear leucocytes but less than the increase in animals treated with antuitrin T. A rather definite correlation was found between the presence of fat droplets in the cellular elements appearing in connective tissue and the presence of fat in the polymorphonuclear leucocytes of the circulating blood

#### CONDIENT AND CONCLUSIONS

In a former publication (11) there was described phagocytosis of fat in the cells which were taking part in the connective tissue reaction in animals which received pituitary thyrotropic preparations Associated with this change were the rapid re placement of fat in fat depots by a clear gelatinous substance and the appearance of fat in many locations including the liver muscle and various epithelial and reticuloendothelial cells. In this study it has been found that after a single admin istration of thyrotropic hormone (antuitrin T especially) there is a rise of the plasma lipoids and of the blood acetone simultaneously associated with changes of the lipoids in many organs. These data further contribute to the belief that fat is being moidly mobilized

Studies of the liver reveal a progressive deposition of fat in the hepsitic cells first appearing within a few hours in the edge of the hepsitic cell bordering the blood sinusoids and progressively occupying more and more of the cytoplasm of the hepsitic cells. Best and Campbell have shown that whole anterior pituitary extract caused fine droplets of fat to appear in the hepsitic cells. This was most striking in 3 days but considerably less after 9 days. This has been confirmed with the thyrotropic preparations used in these experiments.

Anselmino and Hoffman recognized a ketogenic property in thyrotropic hormone but reported that the ketogenic action took place only if the thyroid was present. In contrast Houssay and Rietti reported such a ketogenic substance which acted in the absence of the thyroid. In the investing the contrast that the contrast state of the state of the

reactions which were associated with the changes of plasma fat and blood acetone have been found in thyroidectomized animals just as they were found in intact animals (11)

It has been the belief of Boyd and Wilson that the polymorphonuclear leucocytes did not par tempate in the transportation of fat. In these experiments on the influence of thyrotropic hormone in which there was evidence of rapid transfer of fat there was also evidence that polymorphonuclear leucocytes of the blood stream contained more fat than normally Presumably they par ticipated in the transfer of fat Furthermore polymorphonuclear leucocytes are found in great abundance in fat depots and they also are heavily laden with fat here as well as in the blood stream

By chemical analysis but not by histologic technique Dible and Libman have demonstrated an increase of muscle fat of the fasting animal. I have illustrated elsewhere (xx) an increase of muscle fat by histologic technique however the amount of muscle fat found in these fasting animals is very slight compared with the extreme amounts seen soon after the administration of thyrotronic hormone.

Paulson (16) has described changes in hema toxylin and cosin preparations of the harderian glands, which he interpreted as degenerative. In the studies described here using fat staming tech rique it seems that the changes in the vacuolation of the cells in some animals receiving antuitin Tepresent changes in the amount of lipoid content. The connective tissue reaction found there is probably a part of the generalized connective tissue reaction found throughout the body.

There is a very interesting correlation between the elevation of the plasma lipoids and the appear ance of lipoid in the liver. In 3% to 5 hours the appearance of lipoid in the liver was comparatively slight. If was in these animals that normal plasma lipoid levels were found however after 21 to 24 hours the livers were loaded with fat and in the same animals most of the plasma lipoids were found to be elevated.

In a previous publication (11) I pointed out the correlation between exophthalmos and the changes in fat with associated connective tissue reaction when thyrotropic hormone was given MacKay and Sherrill have shown a diminution of the lipoid content of the bodies of thyroidectom itsed rats while the body weight remains the same Whether the fat is catabolized is uncertain. I have shown that thyroidectomy in guinea pigs and man results in an increase of the prominence of the eyes. This fact also suggests a relationship be tween fat metabolism and exophthalmos

It is a well known fact that in clinical subjects following thyroidectomy the blood lipoids tend to rise and the basal metabolic rate falls. Soley (23 24) and I (9) have both shown that with such a fall of the basal metabolic rate there is an associated increase of the prominence of the eyes in clinical subjects. That there may be similarity in these two groups of circumstances seems possible

#### SUMMARY

The edema and cellular reaction in connective tissue of animals made exophthalmic with thyrotropic hormone have been studied more extensively than in former investigations

Following the administration of thyrotronic bormone the appearance of fat in the liver skel etal and cardiac muscle epithelial cells of several locations, phagocytic cells in the lungs, spleen and lymph nodes and in polymorphonuclear leucocytes and tissue macrophages has been further studied with respect to the sequence of events taking place. The earliest cellular reaction was composed principally of polymorphonuclear leucocytes and macrophages but later lymphocytes and fibroblasts which had transformed from macrophages were most numerous. These features have developed simultaneously with the exophthalmos.

The sequence of appearance of fat in liver cells was demonstrated first as tiny fat droplets aduacent to blood sinusoids and later occupying the

entire cell.

The demonstration of the appearance of tiny fat droplets in the cytoplasm of the thyrold epithelium at a time when the gland was becoming rapidly hyperplastic from the administration of thyrotropic hormone was an observation which was presumed to be related to the other phenome na observed

The plasma fat and blood acetones became ele vated simultaneously with the changes in the

lipoid content of many organs.

Associated with these changes was a polymor. phonuclear leucocytosis. These cells were found to contain an excessive number of fat droplets in contrast to cells in the blood stream of normal animals. It is presumed that these fat laden poly

morphonuclear leucocytes in excessive numbers in the blood stream have some relation to the similar cells which contain fat and are so abundant in fat depots and connective times,

These studies shed additional light on the round cell infiltration described by others a exophthalmic animals and perhaps in man. Clinical observations are briefly discussed in the

light of these findings.

Norr. Since the completion of this investigation there has appeared in the literature study by Rundle and Pecks hich indicates an increase in the fat content of eye muscles in cases of exophthalmic goiter Clin. Sc., 1944, 5 5 74

# SPONTANEOUS GASTROINTESTINAL BILIARY FISTULAS

N FREDERICK HICKEN M.D. and Q. B. CORAY, M.D. Salt Lake City Utah

ONTRARY to accepted opinions spon taneous gastrointestinal biliary fistulas are not medical curosities. Kehr (11) encountered too such fistulas during the routine performance of 2 coo cholecystectomies. Puestow found that 3 5 per cent of all patients having operation on the biliary tract had these troublesome complications. The 15 cases forming the basis of this report represents an incidence of 4.2 per cent. Therefore one of every 25 patients requiring surgical therapy for disorders of the biliary tract will possess some variety of internal biliary fistulas

#### PATHOLOGY

Gastrointestinal biliary fistulas are always secondary to other pathological processes. It is interesting to note that gall stones proved to be the provocative agent in go per cent of reported cases. The close proximity of the gall bladder and choledochus to the duodenum invites the eroding calculi to escape into this portion of the alimentary tract. Six per cent of these spon taneous fistulas are produced by perforating peptic ulcers. If the ulcer is situated on the posterior surface of the duodenum they usually perforate into the choledochus, while those located on the lateral duodenal wall ulcerate through into the gall bladder Gastric ulcers, on the other hand invariably involve the gall bladder. Cancer of the stomach pancreas, gall bladder and common bile duct produces a degenerative necrosis of contiguous viscera so that a variety of internal biliary fistulas result. We have seen one chole cystogastric and one choledochopancreaticoduodenal fistula associated with invasive neoplasms.

An anatomic study of 212 gastrointestinal biliary fistulas reveals the incidence with which the various organs are involved. The gall bladder was involved in 88 per cent, and the common bile duct in 11 per cent. The gastrointestinal component consisted of the divodenum in 69 per cent, colon in 26 per cent and stomach in 44 per cent. Other fistulas were so rare as not to require nota tion.

The biliary dysfunctions following the formation of the gastrointestinal fistula depends largely on the nature of the causative lesion (9). Two courses are open either the fistula closes spon-

From the Departments of Surgery and Roentgenology University of Utah Medic 1 School and Latter Day Saints Hospital

taneously or serious disturbances of the heptobiliary system result. There is abundant evidence indicating that these fistula can and do heal voluntarily Numerous cases have been reported wherein all biliary symptoms subsided after the gall stones had eroded into the duodenum and escaped with the feces. Two of our patients passed very large gall stones per rectum and yet subsequent operations failed to reveal any communication with the intestinal tract. In each instance the gall bladders and duodenum were so adherent to each other that they formed a homog eneous mass of scar tissue. Apparently the gall stones, by a process of ulcerative necrosis had escaped into the duodenum and the fistulous tract had been obliterated by fibrosis. We have seen cholecystoduodenal fistulas close spontane ously as soon as the provocative duodenal ulcer had become quiescent under strict management.

As a rule however the formation of these internal biliary fistulas intensifies the existing henatic dysfunctions by producing a suppurative cholangitis, hepatitis and obstructive jaundice Why do spontaneous biliary intestinal fistulas invariably produce a suppurative cholan gitis while this complication seldom accompanies similar operative fistulas? In both instances regurgitated intestinal contents can be found in the biliary radicals. The explanation lies in the fact that pathological fistulas have a concomitant choledochal obstruction with the resulting stasis of bile. For example, before a migrating gall stone a perforating ulcer or a necrotizing malig nant growth can produce an internal biliary fistula they provoke such an intense inflammatory swell ing of contiguous tissues that a compressive occlusion of the common bile duct occurs. When the static bile becomes infected, the ensuing pancreatitis and cholangitis intensifies the chole dochal obstruction

Cholangiographic studies performed on the operating table indisputably confirm the presence of choledochal obstructions. In all of our opera tive cases the terminal choledochus was so completely occluded that injected diodrast could not be forced through the ampullary opening into the duodenum. Figures 2 3 and 5 reveal that in gested baruum is still incarcerated in the common bile duct 6 hours after the main body of the barum meal has passed from the duodenum into the lower leum and colon. Trace, and McKell

Fig. a. The preploric area of the stomach is occluded by an I distributing proliferrative tumor. The barrium was seen to pass from the stomach through a fattle int the gall bladder but none of the barrium its cried the cystle duct. No barium escaped into the gall bladder until the entire common duct was filled and then the barium seeped along the patent cystic duct. The dilatation of the bile ducts indicates the

## SYMPTOMS

Gastrointestinal biliary fistulas produce no identifying group of symptoms but rather mimic the characterizing syndromes of the parent pathologic conditions from which they arise For example there are no special signs to tell whether a peptic ulcer has merely perforated into the periduodenal tissues or actually eroded into the common bile duct. Likewise an obstructive carcinoma of the stomach seldom announces that it has ulcerated into the gall bladder thereby producing a cholecystogastric fistula. The jaun dice, colic, and septic reactions accompanying a choledochal stone cannot be differentiated from those arrang with a choledochoduodenal fistula So confusing is the clinical picture that the phy sician seldom makes a preoperative diagnosis unless the fistulas have been madvertently discovered by the radiologist (2)

It has been pointed out that the formation of the internal biliary fistula might result in a sudden cessation of all pre-existing complaints (11). This is particularly true if the newly formed fistula effectively drains the static bile. While such fortutious circumstances are not usual they do occur. We agree with Puestow however that the formation of the fistula usually intensifies the patient's discomfort. Nausea vomiting chills, fever, jaundice and colic usually competthem to seek relief

presence of a chronic ampullary obstruction. b, A film taken 6 hour later clearly outlines the dilated chedeoda, and reveals barium in the intrahepatic radicals. Note the complete ampullary obstruction which is present. This finding has been constant in all cases of biliary intestinal fatula.

### DIAGNOSIS

The preoperative recognition of gastrointestinal bilary fistulas depends entirely on the radiologist in reviewing the literature Borman and Rigler found that of 267 fistulas only 86 were recognized preoperatively and in each instance the diagnosis was made by the roenigenologist

Fig. 4. This represents a reflux filling of the common bile duct associated with a duodenal uker. Note the ir regular appearance of the duodenal cap. The biliary radicals were not dilated. A film taken one hour later failed to outline the cholechous for the bardum has escaped back into the deodenum and passed into the lower intest all tract.

In their personal series of 24 cases they made a correct radiological diagnosis in but 37 per cent. Garland and Brown were able to make a diagnosis of gastrointestinal billary fistula in 5 cases which they studied and they assert it is the only method of making an accurate diagnosis.

The roentgenographic demonstration of in gested barium, or gas, or both in any agment of the bluary tract is presumptive evidence of a fixtulous communication with the gastrointestinal tract (12) The most important single finding is the presence of barium in the billary radicals. In only 2 other conditions does barrum have access to the bile ducta. One of these is in the presence of operative internal bilary, fistule and the other is where the barium regurgitates along a gaping common duct when the sphinder of Odd is relaxed. Fluroscopic studies usually afford an effect ive means of different tation.

Cholecystogastric fistulas are recognized by the passing of the barlum from the stomach

Fig. 5. a, The Ingrested barium outflies some storeach—a gavatic provinc frog and an Interpret radional cap. Others e the distended gall bladder as the escape of the diodrant through the first hat he to decoderom. The common bile duct is ell visualization on stores were detected. Q. The choleey-proper the cholanging rate of the contract of contract needing for practically some of the deciders escaped through the ampulse of Vater int the deciders. This film confirms our contention that nots internal billiary fatula have concomitant paternatus the high performs processing the paternatus of the checked of the contract of the checked of the c

through the pathologic atoma into the gall habite (Fig. 1a.) After filling this viscus the contast medium flows through the patent cystic dat into the common ble duct (13). Usually its sphuncter of Oddi is so spasts and the paneras so swollen that they effectively obstruct the amplia of Vater thus preventing the barum from exaping muo the disodenum. This observation is

very important (Fig. 3).

Cholecystoduodenal fistulas present a different picture. The barrum first fills the stomach and then passes through the pylorus into the dood-num whence it gains entrance to the gall bladder through the fistulous tract (Fig. 5). The common bile duct is not visualized unless the cystic duct is patent.

In choledochoduoderal fatulas the baram will be seen to enter the duodenum in a normal manner and then flow through the fatula into the common bile duct (Fig 3 a). It is important to note that the baraum always fills the lower end of the choledochus first and after it becomes filled the barrum ascends along the common bile duct flows through the patent cystic duct, and fills the gall bladder Progress films invariably reveal the barrum to be incarcerated in the common bile duct 6 to 12 hours after the ingested harrum has passed from the duodenum into the lower intestinal tract (Fig 3 b)

Fortunately the reflux regurgitation of the barrum meal along the atonic common bile duct occurs very infrequently and presents certain identifying aigns (13) Fluroscopically the barrum can be seen to pass from the stomach into the duodenum, and as the duodenum becomes distended the barium slowly ascends the ampulla of Vater and completely fills the dilated common duct in a progressive manner (Fig. 4) The barn um however does not remain in the common duct but readily escapes through the gaping sphincter of Odds and goes along with the main barium meal into the lower segment of the bowels. This passage of bile is in striking contrast to the choledochal retention seen in all cases of gastrointestinal biliary fistulas.

The presence of gas within the lumen of the gall bladder or the regional bile ducts furnishes indisputable x ray evidence of a spontaneous gastrointestinal biliary fistula provided one eliminates similar gaseous shadows associated with an emphysematous cholecystitis (16) re gurgitation of gas along an atonic choledochus or through an operative fistula Rees (13) asserts that the reflux regurgitation of intestinal gases through an atonic sphincter of Oddi is so infrequent that it need not be considered. The uti lization of barrum meal usually provides accurate differentiation McCorkle and Fong (10) empha size the fact that in an emphysematous cholecystitis the gas, derived from bacterial action is usually confined within the gall bladder. In rare instances they were able to demonstrate bubbles of gas loculated within the walls of the gall bladder or confined to the pencholecystic structures. This finding indicates an extension of the phlegmonous process. If the films are taken with patient in an upright position one can occasionally detect the fluids in the lower portion of the gall bladder supporting an upper stratum of gas. Duodenal intubation may permit the recovery of Bacillus welchii organisms.

Borman and Rigler maintain that the radiologist is so accustomed to seeing gas in the duode num and colon that he frequently falls to con sider the possibility that isolated bubbles of gas may be incarcerated in the biliary system. If the gas is confined within the common bile duct it

assumes a tubular shape which corresponds to the anatomic position of the choledochus. This gas bubble maintains a constant position which is not the case with collection of intestinal gases. Confirmatory evidence can be obtained by the administration of a barrum meal

When the diagnosis of internal biliary fistulas has been established the radiologist should make an attempt to determine the patency of the intestmal tract (2) If the migrating stones are large enough they frequently produce an acute intestinal obstruction. Scout films may furnish indirect evidence by revealing the presence of gaseous distention loculated pockets of intestinal fluids, or by localizing the offending stones If the clinical picture is not that of complete obstruction the ingestion of a thin mixture of barrum is most helpful Such information is invaluable for the surgeon cannot hope to correct the biliary fistula while the intestinal tract is obstructed The obstructive complication requires primary con sideration

Cholecystcolic fistulas are usually identified by a barrum enema. If such enema does not out line the fistulous tract Faust and Mudgett found that the use of double contrast enema causes the insufflated air to pass through the patulous fistula so that the gas filled biliary system becomes visible

## SURGICAL MANAGEMENT

Patients having internal biliary fistulas are not good surgical risks. Dehydration acidosis toxemia. hypoproteinemia, all combine with the coexisting cholangitis, pancreatitis, and biliary obstructions further to depress essential functions of the liver It requires several days of a carefully planned preoperative regimen before these patients can safely assume the added burdens of an operation To ignore this essential preparation is to invite a high morbidity and mortality rate as indicated by reported cases.

There is no single operation which can be em ployed to correct all of these abnormal biliary fistulas The remedial procedures depend on the viscera involved, the size and location of the fistulous orifices, the presence of obstructive pancreatitis, cholangitis subhepatic abscesses and choledochal stones. Each case must be in

dividualized

Fishilas between the gall bladder and the gastrointestinal tract. Our plan has been to open the abdomen and make thorough palpatory exam ination to determine the location and extent of the provocative lesions ie gall stones peptic ulcers or new growths. The gall bladder and its

fistulous tract are not molested until complete cholangiographic visualizations of the entire biliary system have been made (Fig 5 b) Visual ization is quickly accomplished by inserting a No so rauge needle into the funders of the exposed gall bladder and evacuating its fluid content then about 30 cubic centimeters of 70 per cent diodrast is introduced into the gall blad der and an x my film is made. If the diodrast has escaped into the alimentary tract it clearly out lines the size and position of the fistula. A soft rubber-shod clamp is applied to the sinus tract and an additional so cubic centimeters of diodrast is introduced into the gall bladder As the contrast medium cannot escape from the gall bladder through the fistula it will be compelled to flow along the cystic duct and fill all the biliary radi cals (Fig 5 c) This affords an excellent roent genographic pattern of the bile ducts, noting stones, strictures, and choledochal obstructions. With such information the surgeon can intelli

gently plan the necessary corrective operations When dealing with gastric malignant new growths which have extended into the gall bladder the invasive process is so extensive that resection is out of the question. The neoplastic process has usually compressed the common bile duct and the cholecystogastric fistula affords the only escape for the static bile. To molest the fistula is to invite a biliary peritonitis. We have found that the prepyloric carcinoma effectively blocks the pyloric outlet so that the increased peristals is merely forces the gastric contents through the fistulous tract into the gall bladder thus inciting a fulminating cholangitis By the use of a gastrojejunostomy the gastric obstruction can be partially overcome and the reflux of the irritating stomach contents into the gall bladder is thereby reduced. One of our patients lived for 6 months after such decompressive operation, free from biliary distress, only to die of coronary occlusion.

If the cholecystogastric fatula has been caused by the migration of gall stoces, it is imporative that the functional status of the common hile duct be determined before the fatula is disturbed Should these visualizing cholangiograms demonstrate incarcerated cobedochal stones, which they all too frequently do then the common duct is opened and the offending calculi are removed Now that the choledochas is patent the gall bladder and the fatulous tract can be safely excited, provided the patient is condition warrants this additional surgery. In many instances the removal of the common duct stones still fails completely to remove the choledochal obstruction for the associated panceratus effectively occludes

the ampulla of Vater Dramage of the common duct by indwelling catheters is then region. Should the gail bladder harbor calcul they are removed and drainage of this viscus is institude. When postoperative chokangograms rered its choledochus to be patent, all catheters are moved (?) It has been interesting to observe that in many instances the cholecystogastic fistils has closed spontaneously. Removal of the gall bladder can be deferred until a more opportuse time.

The management of cholecystoduodenal fatulus requires special consideration. If produced by a penetrating peptic ulcer several plans on be followed. Gray and Sharpe advocate gastric resection combined with cholecystectomy and excision of the fistulous tract. Garland and Brown advise a gastric resection without molesting the gall bladder or the festula stating that the abnormal fistulous tract will close sponting ously. We have found that the perforating peptic ulcers are usually so large and so close to the common bile duct that resection of the ulca presents technical difficulties. Merely to remove the stomach does not relieve the concomitant choledochal obstruction and these patients are prone to die from hepatic insufficiency. It seems that the suppurative cholangits aggravated by the associated choledochal obstruction presents

the major problem (1) Our plan has been to individualize each care after complete cholangiographic studies on the operating table are made. In the presence of choledochal obstruction cholangitis, and impaired hepatic function the common bile duct is opened, offending calcult are removed, and catheter drainage is employed. The ulcer and fistult are not molested. Occasionally the excavating peptic ulcer may be so large that much of the duodenal content flows into the call bladder Thus fulminating cholecystitis, cholangitis, and pancreatitis are incited. While it is desirable to resect such ulcers along with the stomach the technical difficulties which it presents seem insurmountable in these ill patients. Likewise, the secondent inflammatory tissue around the base of the ukm precludes closure of the fistulous tract without producing duodenal obstruction. Under such circumstances, prolonged dramage by means of a choledochotomy and cholecystotomy has reheved the jaundice and permitted the uker to beal. Remedial gastric resections can be deferred

until the patient's condition improves.

Choledochodsoderal fittidar The vast majorky of choledochol-duodenal fistulas are produced by migrating choledochal stones or from penetrator peptic ulcers. Experience dictates that the

choledochus does not evacuate all of its calculi through the fistulous tract but some stones may remain in the common bile duct. These offending calculi may be wedged in the ampulla of Vater or incarcerated in the common bile duct above the fistulous ornice In one instance we found the common bile duct to contain 12 stones and the fistulous tract was completely blocked by a mi grating calculous thus accounting for the pa thent's intense jaundice Before the bilary tract is disturbed operative cholangiograms are em ployed to determine the number and position of the offending calculi (Fig 3) A choledon chotomy with removal of the obstructive atones invariably effects a cure. The fistulous tract is not molested, unless it harbors a stone for it invariably heals by the process of fibrosis Usually the stone laden gall bladder is removed at this

Penetrating peptic ulcers on the posterior wall of the duodenum present a much different probkem (Fig. 5) There is such an intense inflamma fory reaction that the resulting fibrosis usually produces a permanent stricture of the common bile duct. In selected cases it seems were to re move the ulcer and stomach and to transplant the resected choledochus into the jejunum If the patient's condition precludes these extensive operations a cholecystogastrostomy or cholecys. tojejunostomy maj suffice. Decompression of the obstructed common bile duct can be obtained by pulling a Levine tube from the stomach through the newly formed stoma so that its tip lies within the gall bladder lumen (8) Constant suction by the Wangensteen apparatus assures complete evacuation of the static bile This procedure has been described by us in a previous

Cholecystocolie fistulas Cholecystocolie fistulas are difficult to handle because of the suppurative cholangitis and hepatitis incident to fetal con tamination. The fistula usually communicates with the bepatic flexure of the colon and the in flammatory reaction surrounding the sames tract is so intense that the resulting mass may produce a partial or complete colonic obstruction One has but to review the literature to become con vinced that such patients do not survive a chole Systectomy resection of the colon and a choice dochotom) all in one stage. The primary consid eration is to relieve the colonic obstruction and prevent reinfection of the biliary tract. This can be accomplished by an obstructive ileostomy which effectively shunts the fecal current. The distal loop provides an excellent channel for trigating the ascending colon with effective

germicides which help to reduce the biliary tract infections. Sulfasuxadine will likewise reduce the bacterial flora of the intestinal tract and make subsequent operations safer. Under such con servative management the inflammatory reaction about the fistulous tract soon subsides, permitting bile to drain into the colon thus relieving the one to the patient a condition permits the fatula can be excised and the offending gall bladder removed Again, may we caution that it is essential to determine whether the common bile duct is patent if not, choledochotomy must be performed Usually the pericolic my famination will be minimal and the size of the fatulous ornice so small that it can be closed without resection of the large bowel. No attempt should be made to establish the continuity of the intestinal tract until the fistulous stoma is com pletely healed While this necessitates multiple operations a living patient is a happy reward

OBSERVATIONS The best treatment for gastrointestinal biliary fistulas 13 prevention This can be accomplished b) removing gall stones before they have time to on tempting goal unitate such undesirable complications Peptic ul cers which have not responded to conscientious medical therapy should be treated by gastric re section before they have had an opportunity to erode into the biliary tract. Farly diagnosis of gastric malignant new-growths combined with radical surgical treatment can minimize these in

There are several problems which must be considered in the surgical correction of gastrointestinal billary fistular First these patients must be carefully prepared to withstand the added burdens of anesthesia and surgical trauma Second the primary surgical consideration is to remove the obstructions of the common bile duct and institute drainage thereby alleviating the biliary stasis (1) Third corrective operations such as excusion of the fatula cholecystectomy or gastric resection can usually be deferred until the patient has made a good recovery from the decompressive operation on the bile ducts.

The mortality in the 13 operative cases was 30 per cent In each of these 4 patients who died extensive remedial procedures were carried out at the initial operation . This convinced us of the wisdom of using multiple operations particularly that of employing decompression of the common bile duct as the primary procedure Since follow ing this plan there were 8 patients with internal biliary fistulas which were operated upon without a death

## SUMMARY

1 Spontaneous gastrointestinal biliary tract fastulas occur in approximately 4 per cent of all patients requiring surgical therapy for disorders

3 Gall stones peptic ulcers, new-growths, and surgical trauma were the etiological agents in 272 studied. This includes 15 personal cases.

3 A preoperative diagnosis of gastrointestinal billary astulas cannot be made from clinical findings alone Careful roentgenographic diagnosus affords the only method of making an accurate preoperative diagnosia. Characteristic roent genographic findings in the various types of in ternal biliary fistulas are described

4. Cholangiograms, performed on the operating table, afford an excellent method of visualizing the gall bladder fistulous tract and entire biliary tree Cholangiograms determine the location and ramifications of the fistula and clearly depict the size of its orifices. Cholangiograms permit ac curate localization and differentiation of existing choledochal obstructions, whether caused by stones, strictures pancreatitis, carcinoma ulcers or periductal inflammation Such visualizing roentgenograms provide the surgeon with an accurate blueprint of problems confronting him.

5 The principles of corrective surgery are discussed with particular emphasis on the value

6 Thirteen patients were operated upon of whom 4 dred a mortality of 30 per cent. Oce patient having a cholecystoduodenal fixed an considered inoperable because of metastatic lesson to the lungs.

# RUPTURES OF MALARIAL SPLEENS UNASSOCIATED WITH EXTERNAL TRAUMA

# R. RUSSELL BEST M.D. F.A.C.S. Omaha, Nebraska, and JOHN F SCHMID M.D.

T this time and for some time to come the frequent occurrence of splenomegaly among our soldiers returning from the many parts of the world may be con sidered a pathological complication of World War II Most of these large spleens are a secondary manifestation of malarna As our soldiers return from the various theaters and suppressive ata brine therapy is no longer required additional dagnoses of malana will be made and more cases of large spicens will be encountered The history will be important but careful examination of the left upper quadrant will reveal splenomegaly in many cases, and thus finding should make alert members of the profession to the potentiality of a higher incidence of spontaneous and traumatic rupture of the spleen. The enlarged spleen assumes greater surgical significance because it is more frable and fragile and also more vulnerable to trauma with resulting rupture and hemorrhage. This is emphasized in the report of Berger in 1902 where in 133 cases of traumatic rupture of the spleen 93 showed evidence of malaria.

More than 60 cases of apparent apontaneous rupture of the malarial spleen appear in the literature prior to 1895 None of these were operated upon, the diagnoses being made at autopsy During the last 50 years, from 1895 to 1945 47 cases have been reported For purposes of analysis, this has been divided into two 25 year periods namely 1895 to 1920 and 1920 to 1945 During the first 25 year period, which in cludes some of the early years in the development of abdomnal surgery, 12 cases of spontaneous rupture of the malarial spleen were lated in a re port by Leighton in 1921 We have undertaken to collect all the cases from the literature between 1920 and 1945 and are able to report 35 cases.

An analyzus of the 12 cases in the period be tween 1895 and 1920 reveals 6 deaths a general mortality of 50 per cent. Five patients were not operated upon, the diagnoses being made at ultopsy a mortality of 100 per cent Seven pa ents were operated upon with 1 death-a ortality of 14.2 per cent. Of the patients From the Department of Surgery University of Nebrasia

operated upon 3 were splenectomized without a death, and a were treated by tamponment with the death of 1 several days postoperatively from anura. In the 2 other cases only exploration with removal of blood clots was carned out as the hemorrhage from the spleen had ceased

An analysis of the 35 cases reported between 1930 and 1945 reveals 18 deaths, a general mor tality of 51.4 per cent. Fourteen patients were not operated upon, the diagnoses being made at autops) a mortality of 100 per cent. Twenty-one patients were operated upon and there were 4 deaths a mortality of 19 per cent. Of these 31 patients operated upon 19 were subjected to splenectomy with 3 deaths, a mortality rate of 15.7 per cent. Of the 2 other cases, one was treated by tamponment with recovery and the other was explored splenic fragments only re outer was exposed openic magnification only to moved, and death followed. Of the 35 cases, 9 patients had been inoculated with malaria for the treatment of lues and only I was diagnosed and subjected to successful splenectomy the other

The literature contains articles and case re ports on spontaneous rupture of both the normal and pathological spleen. As to spontaneous ruptures of the normal spleen we are inclined to agree with Roettig Nusbaum, and Curtis in doubting its occurrence and believe it should be placed in question. The case reports of Sussman (7 cases) and Zuckerman and Jacoby (21 cases) lend some arguments in favor of the normal spicen rupturing spontaneously but probably a more accurate statement would be that such spicens may not have presented discernible signs of abnormality or pathology at the time of exami nation because the rupture occurred at the site of abnormality destroying all evidence of previous pathology The term apparently normal spleen? might be more descriptive. The factor of internal strain or trauma is probably frequently associated with so called spontaneous rupture of the normal or pathological spleen. Such internal strain associated with muscular contractions or intra abdominal pressure changes occurring with coughing specific yawning vomiting effort at the stool and other body exertions must be con

sidered. These academic factors may not be appreciated by the patient as far as their relation to his complaint of abdominal disconficit or pain is concerned. These are not unusual acts, and event the most minute questioning may not always extract the admission of their occurrence.

The onset of spontaneous rupture of the ma larial spleen may be insidious and not present the picture of hemorrhage or shock in the early stages. To be alert to its possible occurrence in unsuspected situations will avoid many fatalities. Analysis and comparison of the two periods in the last 50 years reveal no improvement in the general mortality and this 50 per cent mortality is based mostly on failure of diagnosis. Certainly the technical phases of splenectiony have improved.

In the 3 cases reported in this paper a moderate degree of pain in the left upper quadrant, without a history of external trauma and without the classical signs of homorrhage or shock, would not have resulted in early diagnoses and immediate successful surgical intervention if attending personnel had not been acquainted with the frequent occurrence of splenomegaly among military men and the possibility of spontaneous rupture of the malarial spleen.

CASE t J N Malaria was first diagnosed in this case about January 943, in New Guines. He was treated with quinine, atabrine and plasmochi and during the following nouths had two recurrent ttacks. H returned to the U lted States on rotation in November U lted States on rotation in November 944, and ata-brine was discontinued. I January and March, 945 be had recurrent attacks and was treated with atabrine ing the second attack in March, he went to sick call in the morning and fainted while waiting. He was admitted to the hospital, Plasmodium vivax was demonstrated and atabrice was started immediately. He complained of alight upper abdominal distress. During the afternoon of this day he began complaining of more abdominal distress and weakness. About 30 that evening he collapsed while making an effort I the bathroom. H was again seen by a medical officer. There was increased upper abdominal pais and pain in the region of the left shoulder. The abdomes was distended and there was tenderness over left upper quadrant and lumber areas. There was no fluid wave or shifting deliness. The blood pressure was 65/30, pulse o4, hemoglobia 9 5 grams. With plasme and blood transferior, his general condition improved. Intrampacular atabrine therapy was started. The patient was operated upon under altrom order gas-ether-oxygen anesthesia and the sphen was removed. The peritoscal cavity contained free blood and clots. There were three definite points of rupture on the convex margins of the spicen. He made as unevential recovery

Pathology: The spices weighed 315 grams and was very friable. Serial sections showed small infarct. Effects scopic examination showed focal necrosis of mahighlan believe Mehadles made.

bodies. Maharial paradies were seen. Casz z. H. C. This patient developed malaria in the South Parific in September 1944. He continued on suppressive stabilities therapy until the day of administration it boughtal months into Tow week prior to entering the bospital, he had been constituted and had had no head morement. On this morning, he went to the toller, unless severely and at this time noticed a sucker, naive seen pain leat to the left of the expansion and code to he costal margin. Following this, he felt assemble as recibed several times. He left little weak not remarks had bed to rest a little longer. In the afternoon, became a continued shoboulest pain and marked distress to for region of the left shoulder he entered the hospital.

Examination revealed a soldier in apparent distress His abdomen was quit rigid, more so on the left, and there was marked tenderness in the epigastrium and beseath the left costal arch. The blood pressure was 100/54, house globi I grams with 3,0 0,000 red blood cells per care centimeter Platelets were 140,000 Prothrombia time was S seconds for the patient and 7 5 for the central Lavier of his history and the clinical findings, immediate openion was advised. Intransuccials rabeline therapy was sturd at once. On arriving in the operating room, his blood presented the central contraction of t had been typed so blood was available in few minutes and transferior was given. The blood pressure returned to 90/40 and under nitrous coids gas-ether-oxygen and thesia, the spicen was removed through a transverse shedominal incision. When the peritoneal cavity was opened, large amount of fresh and clotted blood—as esconstruit The spices was pulpated but no break in the capsule was found. Adhesions were very firm to the displaym. The spienic pedicie was gently exposed and a small vets, show t millimeter in diameter, was seen to be bleeding rather freely as a clot was lifted from this area. With the applica tion of a clamp to the velo, bleeding stopped. No break to the aplenic capsule could be ascertained before remoral of the enlarged spicen. There were several areas of subcapa-lar hemorrhage. He made an uneventful recovery led a transfesion was given on the third postoperative day be-

cause of o gram hemoglobia and a 1 per cent hematoch.
Pathology The spilets weighed yo grams. On sicre-scropic section, the germinal centers of the hyperpastic malpighian bodies were partially accordic. Creating forms and schizosta of Phasmodium virus: empression of the control of the contr

i the crythrocytes.

CASE 3. C. B. This patient had his first attack of malaria in North Africa and remained free from recurrent activities. as long as he continued to follow the suppressive state in therapy religiously. On several occusions, he contint tok-ing his daily tablet and within a matter of ceks in sechave recurrent chills and fever On one occasion when is had discontinued his therapy for some days, he lad the opportunity and desire to eat an unusually heavy sel.
That night he awakened about 100 a.m., left senseated, and induced woulding by inserting a finger in his throat While vomiting, he felt a severe, stabblog tale ander the left costal margin and felt very weak on returning to its cot. He was smalle to get much rest because of pale and the following morning reported for sick call. Became a not make any manager provided for sick call. Because pain and traderness under the left contail arch, he was seen into the bospital. On cananization, as calarged and of trader spices was applicated. There was tensionens in the opligatifum and left lumbur regions. Pulse was of spirallic blood resources. All the state of the provided by the containing the contain systolic blood pressure of, distolic 64, hemoglable 15 grams with 4, 200,000 red blood cells. He had an attack of chills and fever soon after reaching his bed, and by the time positive malarial smear was reported. The strict remained very uncomfortable and stated that he isk appelling to the state of accounting was pushing out his ribs. During the seri-leours, his pulse increased to r s, the blood pressure fro-ped t 60/60. With the history of malaria and the large-very feeder subsecutives. very tender spicen with mostle rigidity more parted over

left rectus and lumbar regions without unological symplett rectus and immust remous without unsequest symp-ions or positive prological findings by 2-ray the discoods of a ruptured spicen was made and operation advised or a ruptured speem was made and operation advised Through a transverse incidion the peritoreal cavity was laroupu a transverse manuar the pertument cavity was no evidence of free blood. The apleen openio there was no especial to the proof, the special was greatly enlarged and further emounts revealed a maswas greatly emerged and nutruer caposure revenue a mas-sive subcapaular bematoma. While manipolating the ave succeptual penations, while manipulating the capacile implanted and a large spices for removal, the capsule supported and a surfer bematoms was partially released. At this moment, the pa tentation was partially research are thus mountain the basome general common occasion parter pour puise occasion secta and blood pressure dropped. Plasma was statistical and be accorded immediately. This was followed by a finite occasion. he taperated immediately 1 and was inflored by a note blood, a donor having been selected before operation. He

sage an according recovery.

The pathologist reported a malarial spicen with par asites present.

Three types of rupture have been demonstrated in these cases—namely rupture of capsule with free bleeding subcapsular rupture with massive hematoma development beneath the capsule and rupture of a vein in the aplenic pedicle associated with several small subcapsular hematomas.

An analysis of these cases reveals that the pa tents began having rather sudden mild to moderately severe pain in the left upper quadrant with radiation varying to the epigastrium left lower quadrant and lumbar regions. The onset may occur wille the patient is apparently inactive or while making some alight exertion Nausea or vomiting may be associated with this distress and there may be some feeling of weakness and a de sire to rest and remain quiet. Two of these pa tients had a positive kehr's sign with pain in the left shoulder to which one should attach great agnificance in a suspicious or known case of aplenomegaly as it usually means leakage of blood beneath the left side of the diaphragm. Rallance s sign with percussion duliness in the left upper quadrant is not so important as to indicating blood in this area because of the all ready enlarged spicen. However it is againfacant as to the presence of a large splcen and the posshilly of spontaneous rupture. Tenderness and ngidity on the left side including epigastric and lumbar areas are most significant if there is a history of malaria A history of overseas service with prolonged suppresive atabrine therapy should sert one to malaria even in the face of no history of chills and fever Pulse blood pressure and blood picture changes may not be present in three cases in the early period. With some the typical picture of hemorrhage and shock in addi tion to a suspicion or knowledge of splenomegaly can readily establish the diagnosis.

In the differential diagnosis, perforated or penetrating peptic ulcer ruptured gall bladder mesentene thrombosis, volvulus, renal colic, disphragmatic pleures pancreatitis and coronary

occlusion must be considered, but if the history can relate the heretofore mentioned facts regard ing the possibility of malaria and splenomegaly a prompt and probably correct diagnosis will be made immediately or after a few hours ob-

It is very advantageous in these cases that proper medical management be instituted im mediately on diagnosis and, if possible, before the patient is operated upon A chill occurring be tween the period of diagnosis and splenectomy may not only prove hazardous for the patient but embarrassing to the surgeon and the anesthetist. Anesthesia and surgery are both factors which lend to precipitate recrudescence of malara Strong in his text, cites Manson Baker report ing a reduction of red blood corpuscles by as much as one million per cubic millimeter with a sıngle chili

Quinine dihydrochloride by intravenous route has long been advocated for malarial crises be cause of the rapidity with which a high blood level is obtained. However Hudson has empha suzed the fact that the peak level of quinine used intravenously is over within 30 minutes and that by large intramuscular doses of atabrine a quick more sustained therapeutic level is attained. An effective plasma concentration is reached within 15 minutes and maintained 6 hours by a 0.4 gram intramuscular dose Consistent with this reason ing and in an attempt to avoid the depression associated with large, rapid doses of quinine ata brine dihydrochloride was selected for treatment in these cases Upon diagnosis and before the patient was operated upon a 0.4 gram dose of ata brine dihydrochloride was given intramuscularly half of the dose into each buttock. Thereafter 0.2 gram were given intramuscularly every 8 hours until the patient could tolerate oral medica tion Usually this occurs within 24 to 72 hours postoperatively and atabrine o 1 gram is given three times daily for about 6 days or until 28 grams have been administered. Sodium bicarboande was employed in 1 gram doses three times nate was employed in a gram door direct was daily with the oral atabrine. Each patient was continued on suppressive atabrine therapy (0.1 emergency in these cases, one or more transfusions of whole blood supplemented each opera lusions of whole business supplementation where the rationale of this treatment is to prevent the occurrence of an inopportune chill before during or immediately following the operation to prevent or overcome the cacheria which occurs with the acute malarial attack and to prevent recrudescence of clinical malaria dur ing the convalescent period

The treatment is splenectomy and if tampon ment and auture have no place in the fracture of the normal spleen, they certainly have no place in the management of the more friable malarial spleen. STUMARY

I Splenomegaly is common among military personnel who have served overseas.

- 2 Apparent spontaneous rupture and trau matic rupture of the spicen will be more frequent because the enlarged spleen is more friable and more vulnerable to external trauma and internal STRIDS.
- The apparent spontaneous rupture of the spleen is probably associated with some form of unappreciated or unrecognized external trauma or internal strain.
- A. A series of 12 and a series of 15 cases of spontaneous rupture of the spicen are reported.
- 5 Three additional cases with recovery follow ing splenectomy are reported.

There has not been improvement in the general mortality rate for spontaneous runture of the malarial spicen in the last 50 years. The ferre remains at about 50 per cent and is based on

failure of diagnosis or delayed diagnosis. 7 Splenectomy is indicated. 8 It is important to institute antimalical

therapy as soon as diagnosis is made and before operation if diagnosis has been made.

o Atabrine is the drug of choice.

## EXPERIMENTAL SURGICAL PULMONARY COLLAPSE

DAVID A. WILSON M D., Greenville South Carolina, and HORACE BAKER, M D Durham North Carolina

ARIOUS extrapleural strapping procedures have been introduced into the field of thoracic surgery since the initial report by Tuffier (95) in 1891 These procedures have all arisen as a result of a demand for a simplified operation which can be used in poor risk or complicated cases requiring collapse From a theoretical standpoint the operative procedure is sound in that relaxation in all directions can be secured by an extrapleural freeing of the lung just as in an intrapleural pneu mothorax. Many present day surgeons combine an extrapleural dissection with thoracoplasty for the same reason and find no objection to a combination of operations (Semb)

Extrapleural pneumolysis as a primary procedure, however has met a great deal of criticism, more so in this country than abroad. The criticism appears to be based not so much on the operative approach to the problem as upon the frequency of complications which arise and be cause these complications are so difficult to manage Extrapleural pneumolysis, unlike intra pleural pneumolysis, leads to the creation of a nonserous lined space with a distinctively different physiological reaction. The same end-results may be obtained in so far as collapse of the lung is concerned Churchill (16 17) has stressed the fact that extrapleural pneumolysis, in contrast to intrapleural pneumothorax is an irreversible procedure and should be considered as such. In an attempt to make a reversible procedure out of an irreversible one, air was utilized to maintain the space and met with disrepute. The threat of infection was forever present and sooner or later the air had to be replaced by oil or the space had to be obliterated by a thoracoplasty (Dolley Jones, and Skillen 18 19) Fundamentally then it can be said that the operation of extrapleural pneu molysis is sound but the methods of maintaining the space are unsatisfactory. With this considera tion in mind experimental studies were begun in the Fall of 1943 to discover a material which could be used to fill an extrapleural pocket which would be nonirritating to the tissues, and which would permit the body fluids to organize forming a permanent fibrous pack. An ideal

From the Department of Surgery Dake I niversity School of Medicine and Duke Hospital

material was found in methyl methacrylate commonly known by its trade name of lucite

### HISTORICAL.

Extrapleural pneumolysis is not a new opera The procedure was first described by Tuffier (95) in 1891 The first recorded operation in this country was performed by J B Murphy in 1808 In 1910 Tuffier (99) reported 3 cases and noted the need for some material to maintain the collapse In 1914 (97) he reported 11 cases in which the cavity was filled with the patient sown fat. In this series there were 4 deaths and only 1 cure. Bull also used fat in o cases with healing in Morrison Davies reported 4 cases improved by filling with fat. Fat was soon discarded as a filling material because it was too difficult to obtain in an emaciated person because it was too

soft and because liquefaction occurred

In 1913 Baer (7) recommended extrapleural pneumolysis because of its simplicity and because it avoided extensive skeletal operations. He em ployed a paraffin mixture, consisting of 75 cubic centimeters of parathn with a melting point of \$8 degrees centigrade and 25 cubic centimeters of paraffin with a melting point of 50 degrees centigrade plus I gram of bismuth carbonate and oc gram of violorm. The paraffin mixture was sterilized by vapor sterilization on 2 successive days for 1 hour and warmed before using. The mixture hardened at body temperature and met the chemical requirements better than fat. Sauer bruch (79 80) was first to carry out a large series of cases with this material and Nissen (6, 66 67 68) and his co-workers, pointed out indications and shortcomings of the paraffin pack. Complete obliteration of the pleural cavity is of prime necessity since the obliterating material causes a marked foreign body reaction which combined with gravity may result in a tear of the parietal pleura with penetration of the free pleural cavity The same process leads to a necrosis of the lung overlying adjacent thin walled cavities. This most dreaded complication results in a severe in fection and demands immediate removal of the pack. The pressure necrosis of the lung overlying thin walled cavities is attributed to the interruption of venous and arterial communications from the thoracic wall through the pleural adhesions

Fig. Roentgenogram of chest indicatopsy of rat No. 7 showing collapse of right lower and middle lobes 9 weeks

after insertion of methyl methacrylat mold into the pictural cavity

the blood supply from the lung to this area having already been interrupted by the cavitation. Too thits attention has been given to the foreign body reaction created by parafin. It is our opinion that this is of greater importance than the interference with the blood supply.

Baer (78,0) recommended performing the operation through an anterior incision. Nissen preferred a posterior approach and limited the mass to 500 or 600 cubic centimeters. Head has recently advocated the paraffin pack for closure of large apical cavities which are prone to retreat against the spine or mediastinum and remain patent despite extensive thoracoplasty procedures, including removal of the transverse processes and costal cartilages. He observed a higher percent age of favorable results than when thoracoplasty was performed as an initial operation. He also advocated the initial paraffin pack as a less dangerous procedure with a good chance of cavity closure. Furthermore he felt that thoracoolasty performed after initial paraffin packing was more ant to be effective and attended by less complications because of the reduction in size of the cavity and stabilization of the mediastinum. He reported at patients selected as being suitable for initial paraffin filling. Of these 31 24 had conversion of sputum from positive to negative. Three were improved 2 were worse and 2 died. Sixteen had large apical cavities, 6 of which were converted by packing alone and 7 others by packing and thoracoplasty In 4 cases the paraffin perforated the lung and had to be removed.

Schlange, Sauerbruch (79,80) Casper and Matson (54,55) advocated compression with an extrapleural pack of plain gauze. Matson (54) in 1938 in a preliminary report advocated an extrapleural gauze pack in apical and subapical soft walled cavities of recent origin, preferably less than 4 to 5 centimeters in size with a patent bronchus. In general he employed the gaure pack in those cases in which extrapleural pneumothorax would at that time have been the logical procedure to utilize that is, in those patients with tuberculous cavities or areas of infiltration is either one or both upper lung fields. The collapse was selective in character and he felt that the postoperative management was relatively simpler than extrapleural pneumothorax. Of 81 patients reported 54 had conversion of the sputum, 15 were considered clinically well after the pack was removed There were 4 deaths none directly attributed to the operation. Infection occurred with the formation of a purulent exudate in 18 cases and in 16 removal of the pack was necessary Removal of the pack was followed by thoracoplasty in a large percentage of these cases.

Shivers, Architaid (4,5) Coffaerts and Winther (34) Sebrechts, Alexander (2, 3) and Churchill (10 17) have advocated filling an extra pleural cavity with pectoral music detached from the chest wall and humerus. The stread of coracoid attachments were preserved with the main blood supply in order to oliminiat stropty of the muscle Archibald (4,5) Buther, Schner Douglass, and Merkel combined muscle packing

Fig. 2. Roentgenogram of chest and autopsy of rat No. 16 showing collapse of upper 3/ of right lung 8 weeks after

insertion of methyl methacrylate mold into the pleural cavity

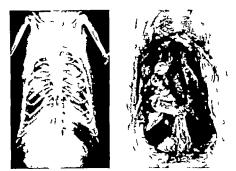

Fig. 3. Roentgenogram of chest and autopsy of rat No. 7 six months after insertion of ¼ inch methyl methacrytate balls into the pleural cavity. The balls are still free in the pleural cavity.

with thoracoplasty removing the anterior por tons of the second third and fourth ribs while Goffaerts and DeWinther performed an extra pleural pneumolysis through an anterior approach resecting a portion of the third rib and pulling the pectoral muscle through the first intercostal space Alexander (3) and Lilienthal (51 52) advised a supraperiosteal and subcostal filling of muscle performed through a curved

antenor incision in preference to an extrapleural packing. In this modification the periosteum of the first three or four ribs is stripped free and is displaced medially by the pack. Re-expansion is prevented by regeneration of the ribs in this location deep in the thorax. The advantages of this modification over extrapleural stripping is that there is less danger of tearing the pleura and the extent of the pulmonary collapse is readily

Fig. 4 Photomicrographs of the pieura and lung in contact with methyl methacrylateria, left, weeks, b, 6 months. X195

controlled by the amount of periosteal stripping and is not limited by the presence of tough extra pleural adhesions. The indications for supra periosteal and subcostal packing are extremely limited. The limitations are much narrower than those of extrapleural pneumothorax and more dosely approach anterior thoraccephasty in opera tive technique in performing thoraccephasty it is doubtful if any case of pulmonary tuberculosis is more suitable for this procedure.

Gwerder Jessen (46) Miller and Oughteron and Harvey (70) used an inflated rubber balloon inserted in the extraplieural space for the treat ment of tuberculous pulmonary cavities. Haspit, Harvey and Oughterson (40) used a similar balloon placed supraperiostically for the treatment of nontuberculous cavities. This temporary collapse was maintained until the patient a condition permitted a thoracoplastiv or an unroofing operation. Infection occurred in the majority of patients, and the postoperative management was complicated.

The maintenance of an extrapleural collapse by means of ar refills is of relatively recent inception. Mayer in 1913 first demonstrated that it was possible to do a complete extrapleural stripping of the lung including the pleura over the dapphragm. Jessen (47,48) and Ricckenberg reported a series of successful cases. In 1923 Romanis and Rivoere (74) reported an extensive extrapleural stripping with re-expansion because of delay in matriating the refills. In 1932 Jacha and Sebesty en advocated extrapleural preumothorax in conjunction with an unsuccessful intrapleural preumothorax. Serious attention was not given to extrapleural preumothorax until the poblications

of Graf (35,36) Schmidt (82 83) Moraldi, \max (65 66 67 68) Michelmon and Zormi between 1933 and 1938 In 1936 Graf (35,36) reported 107 cases with favorable results. In 1037 Schmidt (83) reported 155 cases and increased the number to 544 by May of 1939 (Adelberger Thesa, Bellinger Gaubatz, and Sauer) Large senes of cases did not appear in the American literature until 1938 (Overholt and Tubbs, Belsey) At first received with considerable enthusiasm it immediately became apparent that air was not an ideal material for the maintenance of an extra pleural pocket. Unlike the serous lined intra pleural cavity the extrapleural space was maintained with difficulty, complications were frequent and re-expension failed to occur following discontinuance of the refills. The space then had to be obliterated by thoracoplasty or converted to an oleothorax with its ever attendant dangers Dolley Jones and Skillen (1819) m a compre hensive survery reviewed the results of over 2277 cases gathered from 27 clinics where extrapleural pneumothorax had been in use for more than a years. The results varied with the character of the patients selected for operation. Conversion of the sputum occurred m only approximately 53 per cent of the patients and 11 per cent were dead Early conversion of the pocket by means of oleothorax was advised in order to control and maintain the collapse, to reduce the expense of refills, and to minimize the chances of infection. On the whole the report was not favorable

## EXPERIMENTAL STUDIES

In the search for an ideal substance to be used as a packing material for an extrapleural space certain fundamental considerations were appar

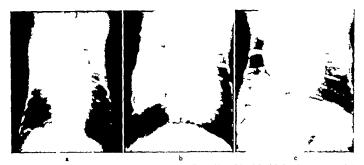

Fig. 5 Roentgenograms of chest of dogs abowing a, collapse of apex, b, collapse of middle portion, and c,

ent. Since the material chosen was to be left in the extrapleural pocket permanently thus establishing an irreversible collapse comparable to thoracoplasty (1) the material should be nonunitating to the tissues, both in the immediate postoperative period and in later stages (2) it should be noncarcinogenic and nonantigenic (3) the material should be of light weight so that a large quantity could be introduced without danger of penetrating the pleural cavity and lung (4) it should be insoluble and not subject to chemical change in the tissues (5) it should offer little if any resistance to x rays (6) it should be capable of being premolded in such a shape that varying sized cavities could be filled through a relatively small incision

The various metals and nonmetals which came under investigation included aluminum tan talum vitallium preserved cartilage, stainless steel celluloid and methyl methacrylate. The metals, especially tantalum and vitallium, were considered ideal in so far as the tissue reaction was concerned but were discarded because of the weight and expense. Celluloid and methyl metha crylate are both relatively inexpensive and light Both have been used in orthopedic surgers and in neurosurgers to repair bone defects but nothing to our knowledge has been reported concerning their use in thoracic surgery Celluloid was first used by Fraenkel in 1890 for the repair of cranial defects and gained wide popularity for this purpose in the early part of the century Experimentally the tissue reaction has been shown to be slight. Immediately after the

operation a serosanguineous exudate formed

collapse of lower lobe of the right lung by means of methyl methacrylate balls inserted into an extrapleural pocket.

about the celluloid which frequently required aspiration. Six days after implantation the celluloid was surrounded by granulation tissue containing newly formed vessels and polymorphonuclear leucocytes. After 4 weeks laminated connective tissue still infiltrated with inflammatory cells was present. Nev reported 300 implants with but 5 infections. If infection did not occur encapsulation took place. Several operators have found little reaction after several years. Funke (29 30) however found that the celluloid lost its elasticity became brittle and crumpled, and chemical analysis showed that camphor was lost from the implant. If has therefore been discarded

Methyl methacrylate is an acrylic resin manu factured from acetone hydrogen cyanide and methanol in the presence of sulfuric acid. The end product is a clear liquid called methyl metha crylate monomer Under exacting chemical and physical conditions polymerization takes place giving rise to the clear solid form which is mar keted commercially under the trade names of lucite crystallite, plexiglass, and vitarilic. the finished form methyl methacrylate exhibits a tensile strength of 6 000 to 9,000 pounds per square inch. It is thermoplastic and softens when heated to temperatures above 220 degrees Fah renheit (ros degrees centigrade) It absorbs only a small amount of water without changing its chem ical composition. Methyl methacrylate is soluble in esters, ketones ethylene dichloride and chloro form it is not affected by weak acids or alkalis

Methyl methacrylate was first used in dental prosthesis and found to be nonirritating when in contact with the mucous membranes over a long

Fig 6. a, Lung f dog No. 5 removed at topsy 5 months after extrapleural packing with methyl metha crylat balls.

period of time. Kleinschmidt in January, 1940 was the first to report its use in experimental animals, to repair skull defects. In the first lew days the plate was found to be surrounded by a small amount of serum which rapidly organized, forming a definite capsule of hivaline connective these. There was little inflammatory reaction and no foreign body response even after the presence of infection. Kahn believed the material could be safely used at the time of a primary repair of a perforating wound of the skull, and even in the face of infection the plate need not be removed.

With these studies in mind, methyl methory late appeared to fulfill the qualifications of a satisfactory filling material to maintain an entra pleural collapse of the lung Animal experiments were begun in November 1044 to determine the reaction of methyl methacrylate implanted into the extrapleural space and into the pleural carrie Operation was performed on 30 adult rate and 10 does. In some of the rats collapse of the individual lobes was secured by implanting a mold of the lobe to be collapsed directly into the plean cavity (Figs. 1 and 2) In other rate a portion or the entire pleural cavity was filled with 1/4 inch balls introduced through a small opening in the chest wall (Fig 3) The operation was performed with positive pressure anesthesia under stelle precautions. In the postoperative penod fre quent x ray films of the hings were taken. The rats were killed at intervals of from 10 days to 8 months and postmortem examinations were made. A little effusion was demonstrated follow ing the introduction of the methyl methacrylate into the pleural cavity but the animals tolerated the material well and except for some shortness of

breath in the first few days, activity was normal. Histological studies of the pleura and mode is not live in the property of the pleura and mode is not live in the property of the property of the line (Fig. 4). In 26 rats at electasis was present without inflammation. In 4 rats a poeumono process was present with multiple small abscesses confined to the attelectatic portion of the long Empyrems was associated with 2 of these cases (2) A minimum of pleural reaction characterist in the first few days by the formation of a small amount of clear fluid around the implants accompanied by a swelling of the metodelism and

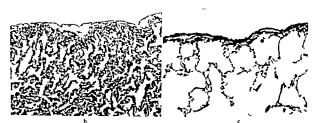

Fig. 6 b Photomicrograph of section through collapsed rea of lung compared tith normal lung

proliferation of the connective tissue in the submesothelial region. The mesothelial lining of the pleurs remained intact in most instances and a few large cosmophilic staining cells resembling mast cells were observed in the submesothelial region. There was no round cell infiltration or guant cell formation (Fig. 4)

In 18 of the rats the fluid around the implants became organized into a thin film of hyaline connective tissue infiltrated at the peripher, with newly formed capillaries and a few chronic in fammator, cells. In 10 rats the implants were still free in the pleural cavity at the time of autopsy (Fig. 4) Two rats died on the fourth and twelfth postoperative days and autopsy revealed empyema with the formation of abscesses and granulation tissue around the lucite balls and in the underlying lung tissue.

An extrapleural collapse was performed on 10 healthy does which were then followed clinically and roentgenographically for 6 to 8 months (Fig. Approach to the extrapleural space was easily secured between the ribs but because of the tissue paper character of the parietal pleura its close attachment to the periosteum of the ribs, and its extension high into the neck, classical extrapleural stripping in the dog was found to be extremely difficult. Dissection of the inner periosteum from the rib was frequently necessary The space when developed, was filled with solid 34 inch methyl methacrylate balls. In 8 of the 10 dogs a serosangumeous exudate appeared within 48 to 72 hours postoperatively resulting in moderate swelling of the operative site and requiring aspiration in 1 dog Infection in the operative incision occurred in 1 dog requiring open drainage. Healing eventually occurred how ever with penicillin therapy and without removal of the lucite balls. There were no deaths in the series of to dogs and no evidence of any systemic reaction after the immediate postoperative period.

Autopsies revealed a localized atelectasis of the lung adjacent to the extrapleural pack (Fig 6). There was a moderate thickening of the mesothelial layer and microscopically some proliferation of the submesothelial connective tissue of the visceral pleura similar to that observed in the rats. Adhesions between the visceral and parietal pleura were absent in 7 of the dogs. In 3 fine string like adhesions were present. The methyl methacrylate balls in the extrapleural space were fixed in a dense mass of hyaline connective tissue (Fig 7).

### EVALUATION

Methyl methacrylate introduced into the pleural cavity and extrapleural space of experi-

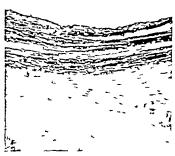

Fig. 7 Photomicrograph of connective tissue surrounding the methyl methacrylate balls inserted into the extra pleural space ×127

mental animals is well tolerated. It is light weight, readily available, inexpensive and non irritating. Its reaction is characterized by the production of a thin capsule of hyaline connective issue.

The adaptation of methyl methacrylate to clinical surgery is opening new horizons. At the present time it is being used to repair cranial defects and in reconstructive surgery (100 72) Our studies have been concerned with its adapta tion to thoracic surgery. At the present time 8 patients with pulmonary tuberculosis have been operated upon methyl methacrylate has been used as a filling material to maintain an extra pleural collapse. The results in these cases have been sufficiently gratifying to warrant its continued use and will be discussed in a later paper The use of this material we believe will save from discard an operation which has interested surgeons since the procedure was first described in 1801 It fulfills a need not satisfied by paraffin, muscle, fat, oil gauze or air It adds to the surgeon's armamentarium a single stage procedure which because of its simplicity can be used in complicated and poor risk patients with pulmonary tuberculosis.

### SUMMARY

Experimental studies utilizing methyl metha crylate implanted into the pleural cavity and extrapleural space of 40 laboratory animals have been presented. The reaction of the pleura and extrapleural tussue has been demonstrated. Its

use is suggested in the treatment of pulmonary tuberculous

## THE RH FACTOR-SEROLOGIC BACKGROUND AND CLINICAL APPLICATION

S. MILES BOUTON IR, M.D. M.S. Rochester New York

HEN a foreign material such as, for example a disease-producing microorganism enters the human body the latter is likely to respond with the formation of substances which destroy the in vader These substances, known as antibodies, usually function by agglutinating or by dissolving the foreign material. Antibodies may be absolutely specific in that they will attack only one particular antigen or toxin or micro-organism. Certain antibodies may be present in the body from birth so that the first invasion by the antigenic material is met by the already available defense force. This type of body reaction repre sents the process of immunization or if the antibodies are fully developed a state of immunity

The antigen-antibody reaction which apparently is an attempt by nature to protect the body against noxious influences does not always proceed without damage to that body. If the total bulk of the affected foreign material or micro-organisms is sufficiently large, the agglutinating process within the bloodstream is apt to produce so much dead material in the form of coarse particles that capillaries may become obstructed and kniney function be impaired or if the dead material is broken down too rapidly a complicated systemic reaction to these 'denatured" substances may set in manifested by chills, fever flushing chest and back pains, etc. If the foreign substance happens to be erythrocytes introduced with a transfusion of whole blood or of red cell resuspensions, there may be jaun dice reflecting rapid destruction of the foreign red cells.

The so called A and B substances found either separately or together in the red blood cells of most human beings are in a sense antigens and they determine the four blood groups (A, B AB, and O the last named being the group whose red cells contain neither of these two substances)1 They are also called agglutinogens, because the

cells containing them are agglutinated (although they may be and frequently are hemolyzed Le dissolved) when brought into contact with ag glutinins (antibodies) which are specific for the A or B substances and which are normally present in the serum of a part of the human race. Nor mally if an individual s red blood cells contain an agglutinogen his serum does not contain the corresponding agglutinin as there would then obviously occur destruction of the red cells within their own serum. That is to say anti A applu tinin is absent in individuals whose red blood cells contain A agglutinogen The normally con stant presence however of anti A agglutinin in the serum of a person with B cells renders that person's blood incompatible with that of an m dividual containing A (or AB) cells

It is common knowledge that a transfusion reaction of severe type is practically inevitable if blood from a different group is introduced into the blood stream of any individual except one whose serum contains no agglutinus capable of destroying the injected red cells as it is this destruction of the foreign cells which almost invariably is the cause of the reaction. This is the reason we call an individual a 'universal donor' ('blood group O') if his red cells contain no A or B agglutinogens so that the latter cannot be destroyed by pre-existing anti A or anti-B ar glutinins in the serum of individuals receiving such a donor's blood it is furthermore the reason we call an individual a universal recipient ('blood group AB') if his serum contains no anti A or anti B agglutinins, so that it cannot agglutinate or otherwise damage foreign red cells containing either A B or A and B agglutinogens.

In pregnancy a mother may carry a fetus whose blood group will differ from hers because of inheritance from the father as father and mother do not, of course always represent the same group. One might therefore expect that the mother's already present anti A or anti B (or both) agglutinins would create havoc with the fetal red cells and red cell producing tissues, if the fetus has the corresponding agglutinogens within its cells, as such agglutinins readily pass through the walls of the placental villi which separate maternal and fetal blood. This actually does

From the Pathologic Laboratories, St. Mary Horpital, Dt. Boaton, director Toe A group incindes subgroups (A, A, A, A) whose existence occasionally is responsible for uncropulated "hitz algoot" incompatibility. These details do not contribute to this discussion and are therefore not considered further here.

occur, but only very rarely and the result may then be damage to the fetus in the form of "ery throhlastosis foetalis, which may take the form —depending in part on the seventy of the dam age, in part on the organ or thane chiefly affected in the infant, such as bone marrow or liver—of "hydrops foetalis," with death of the baby prior to or soon after delivery or of profound and progressive anemia, or of "feterus neonatorum or possibly of a combination of these pathologic changes. (For purposes of didactic clarification only the familiar blood groups are invoked in this introductory discussion. More specific data follow)

Almost all individuals are 'secretors, that is to say, they possess the A or B substances not only in their red blood cells, but also—and actually in much greater concentration -in other tissue cells, and continue, moreover to produce these substances in large amounts, so that they are even excreted in saliva and gastric juice (these fluids are the chief source of some commercially prepared A and B substances) When small amounts of anti-A or anti-B agglutinins are introduced into the bodies of 'secretors' gradually and by a route other than direct introduction into the circulatory system, they are readily neutralized or fixed by the abundant A or B agglutinogens within the body tissues before agglutination of the red blood cells, with their much weaker A or B concentrations, can occur This is the reason why group incompatibilities of the A and B type between mother and fetus almost never occur. That is to say the red blood cells of secretors are sur rounded, so to speak, by a defense wall which is breached, or rather droumvented only by the therapeutic device of intravenous administration of foreign blood in large quantity

That trouble due to incompatibility of this type cours at all is due to the fact that run individuals are inco-secretors, that is to say they appear to possess A or B agglutinogens only in their red blood cells, which are thus exposed to the action of any anti A or anti-B substance which may either through the placents in the case of a fetus, or by transfusions in child or adult, get into the blooditream. In other words, there is no available A or B substance elsewhere in the body to neutralize the anti-A or anti-B authodies before they reach the red cells. In the fetus the effect may be erythroblasticals, in the recipient of

a transfusion it may be a transfusion reaction.
The 'Rh factor' is an antigen which for all
practical purposes may be considered to be entirely similar to the A and B substances, and, like
these, it is also found within the red blood cells.

The two points of prime importance in casidering the clinical problems related to this rel blood cell factor are (i) that it crists only in the red blood cells that is to say all individuals on non sectors? in regard to the Rh factor (i) that there does not exist normally any anti-Rh satisfact or agglithms in human screen.

The implications as to the first point are that any Rh-positive individual (i.e. one whee red blood cells centain the Rh factor) is behicked exposed to the destruction of his red cells if these are brought into contact with an anti-Rh aguitain as his other tissues contain no Rh sustance to neutralize such a specific aggiutain and thus to protect his red cells.

The implications as to the second point are that even though all Rh-positive individuals are nonsecretors, they are ordinarily in no danger at all as no normal individual has anti-Rh agglutinins in his blood. Consequently blood from Rh positive and "Rh-negative (Rhnegative meaning simply absence of the Rh factor in the red blood cells by corollary group 0 blood might be termed AB-negative viduals can safely be given to Rh-positive or Rh negative individuals interchangeably with no risk whatever provided, of course, that donor and recipient are compatible as to their A and B groups In other words, there is no need to consider Rh compatibility as far as sumediate danger is concerned, in contrast to the situation as regards the A and B blood groups, and this fact explains also why ordinarily only the usual typing and cross matching procedures (for A and B substances) need be done to avoid transfusion reactions.

The Rh factor is dominant and follows the Mendelian laws of inheritance, that is to say in a mating of a genetically fully Rh-positive with an Rh-negative individual, the progeny will invariably be Rh positive The Rh-positive proreny however may carry a "hidden or recensive Rh-negative gene, and if such an individual is mated with an Rh negative individual, some of the progeny will be Rh-negative. An individual whose blood is Rh-positive and who carnes only Rh-positive genes is "homozygot." An individual whose blood is Rh negative and who carries both Rh positive and Rh-negative genes is hetero-If the blood of one partner in a mating therefore, is Rh-positive and that of the other is Rh-negative the blood of the progeny will be either Rh positive in all children if the positive parent is homozygot, or m one half of all possible children if that parent is heterosygot.

In pregnancy there may be, and probably frequently is, some intermingling of maternal and

fetal blood through leaks in a traumatized pla centa. In the case of an Rh negative woman carrying an Rh positive fetus such intermingling is at first quite unimportant in contrast to the situation of A or B incompatibility with a non secretor fetus because the mother normally has no anti-Rh agglutinin with which to damage the fetal red blood cells. For this reason the first child in such matings is almost invariably normal, even if blood intermingling takes place in such an instance

The introduction of Rh-positive red cells into Rh-negative blood will however initiate the production of anti-Rh antibodies so that prolonged or repeated contact of such blood with Rh positive red cells will eventually produce incompatibility The latter will take the form of destruction of the Rh positive cells with resultant transfusion reaction on the part of the antibody-producing Rh-negative recipient of such cells, or damage to the fetus (e.g. erythroblastosis) in the case of antibodies formed by the Rh-negative mother entering the circulation of her Rh positive fetus, which as a non-secretor' in respect to its Rh factor cannot protect its red cells from the mother's antibodies by neutralizing the latter

In other words, once sensitization of an Rh negative individual has occurred the status of that particular individual in regard to the Rh factor is the same as his or her status in regard to the A and B substances.

The mitial lack of anti-Rh antibodies explains the fact that the first child in Rh-positive-Rh negative matings is normal and that transfusion reactions due to Rh incompatibility develop only gradually with only mild manufestations at first after repeated transfusions of Rh-positive blood into Rh negative individuals, and usually after a lapse of time necessary for the development of the anti-Rh antibodies. Of the white population about 87 per cent are Rh positive (negroes 92 to 95 per cent, Chinese and Japanese, 99 per cent) Actually the proportion of erythroblastic infants born of that population is considerably less than would be expected statistically because (x) there must (on the basis of existing knowledge) be direct contact between maternal and fetal blood to initiate development of anti-Rh antibodies, presupposing placental leaks, (2) individuals differ in their ability to develop sufficiently large concentrations ( titers") of antibodies to cause damage (3) the relatively small number of women in our present population having more than one or two children naturally diminishes the likelihood of erythrobiastosis.

On the other hand, the increased use of blood transfusions in present-day medical practice has increased the risk of sensitizing Rh-negative individuals by giving them Rh positive blood so that it occasionally happens that an Rh-negative woman will produce erythroblastosis in her first born because she received Rh positive transfu sions previously, thus enabling her to develop anti Rh antibodies in preparation so to speak for her Rh positive child. Conversely if the husband of an Rh-negative woman is heteroxygot the first 2 or 3 children may be Rh-nega tive so that the first Rh positive child, even though it represents the third or fourth preg nancy is just as safe as if it were the first born as there will have been no preceding antibody stimulation Theoretically at least an Rh negative woman who as a child received intra muscular injections of Rh positive blood could concervably be sensitized, but the likelihood of serious consequences of the form herein discussed is certainly remote

An apparently complicating feature in the Rh picture is the more recently well established existence of several Rh types which may appear separately or in several combinations. This deserves mention in this connection only because the general medical literature occasionally refers to these subtypes by name, and because even if only in rare instances, it is possible for an Rh-positive woman to have an crythroblastic Rh positive infant on the basis of an Rh incompatibility. This would be because the father and mother happen to represent different Rh types, with the infant inheriting from the father an Rh factor absent in the mother's blood.

An additional complicating feature is the discovery of still another blood factor (more cor rectly red blood cell factor) which has been called the Hr factor in this country and is apparently identical with the St factor of British investigators. It is present (as determined to date) in the red blood cells of all Rh negative individuals as well as in those of individuals possessing certain of the Rh factors, that is to say about 75 per cent of the white population is Hr-positive (this includes the 13 per cent Rh negative portion as well as all Rhe Rhe and Rh types') The corresponding Hr antibody can contribute cases of incompatibility between Rh positive or Rh-negative letus and Rh positive mother Thus, it is necessary to know of this Hr factor and its antibody to avoid ignoring the possibility of incompatibilities when ordinary Rh

These last three are, of course, "Rh-positive ; see appended blife-egraphy for terminology

and anti-Rh testing seems to indicate freedom from danger

To the ranks of Rh-positive—Rh-negative in compatibilities must therefore be added those occurring among Rh subtypes the Hr positive—Hr-negative combinations antibody action on nonaecretors in the regular Landstener groups, and so far not mentioned those relating to the M N and P factors, the latter three long known in paternity testing but otherwise hardly of

significance clinically

The A and B nonsecretors, however chiefly of theoretical interest, were discussed earlier in this report only to furnish a more readily comprehensible groundwork for the discussion of the Rh and related problems. From the point of view of frequency incompatibilities induced by preg nancy or multiple transfusions remain chiefly an Rh positive—Rh-negative problem. Actually over on her cent of all cases of infant envithroblastosis occur with Rh-negative mothers, with the remaining less than 10 per cent of cases distributed among all the other aforementioned incompatibilities, and within this lastnamed minor group the Hr factor is probably responsible for the majority of cases.

Laboratory procedures for determining the Rh factors and their antibodies are similar to those long in use in determining 'standard blood groups, but are more difficult to perform and thus are subject to misinterpretation A frequent error in many typing laboratories is the reporting of an Rh-positive individual as Rh negative, as many improperly controlled sources of such reports still use commercially advertised typing serum of animal origin which has the triple faults of (1) not reacting to all Rh types, (2) re acting poorly in most or many instances in which it should produce readable reactions and thus causing false negative readings, and (3) of producing false positive reactions in Rh negative infants. Aside from the last named occurrence no anti Rh typing serum should, theoretically ever give a false positive reading in a properly conducted test.

Many surptisingly weak reactions is time obtained from blood of women hearing markedly erythroblastic infants, and many fatse negative reactions in tests for anti-Rh antibodies have been explained by the concept of so called 'blocking antibodies', meaning substances in the serum to be tested which attach themselves to Rh-posture red cells (or more correctly to the Rh factor in those red cells) without causing agglutination thus preventing ordinary agglutanting antibodies from

producing a visible reaction. It is now becoming apparent that such blocking antibodies run parallel and may be identical with the anti-Riantibodies which destroy Rh-positive red cells as viro and that this test tube phenomenon may reflect artificial differences between reactions occur ring within the bloodstream and those observed in the laboratory This should also serve to emiss at least in part why the customary cross-matching" procedures for the regular blood groups were done these many years without discovery of the Rh factor and its antibody Such differences are further indicated by the fact that the test tube reaction upon which we rely almost entirely in determining the Rh status is agglutination, whereas the reaction within the human body appears to be almost entirely one of bemolysis or at least of a combination of these two processes. Another potential source of confusion is the fact that Rh antibodies appear to react best at body temperature, Le they are "warm agglutinhs, in contrast to anti-A and anti-B antibodies, which Recently developed cold agglutinina. modifications of testing methods have larger) overcome these handscaps, and Rh typing is now an adequately sensitive and dependable test with the right reagents and in trained hands.1

A so called 'biologic test' has been described and recommended, consisting of the introduction of a small amount of Rh-positive blood (e.g. oc.,) into the circulation of an Rh-negative helividual with testing of the latter's serum for evidence of subsequent hemolysis as an index of the presence of antibodies, but this procedure is considered by the writer to be reprehensible and at this time unjustified as it obviously tend to attinulate antibody production where there was none before. It is well established that minute amounts of Rh-positive red blood cells (sorth as are assumed, for example, to escape mto maternal blood through damaged placental villi) may suffice to situalists such a reaction

The only good sources of spontaneously or curring dependable anti-Rh typing serum at present available are women who have recarly given birth to crythroblastic infants, and, mak more rarely Rh negative individuals who have reacted to multiple Rh-positive iransfusors. Such women should therefore, if health, be urged to contribute blood while their anticoly titer is high and can be paid for such deattless at the usual rates, as the Blood Grouping Laton-

The appended bibliography It is essential, in this writer's episode that any inheratory or bised bank worker was propose sub-III (year that any inheratory or bised bank worker was propose sub-III (year the paper seeking with those return mentionations, or he interest proposed to a topical supresentation, even the greenest actions in

tones in Boston (Dr Diamond) will on receipt of such blood credit the sender with typing serum

in proportionate amounts

New sources of high titer typing substance in probably ample amount are now available obtained by fractionating serum from Rh-negative individuals with artificially stimulated anti Rh autibody production. This procedure is the same as, or similar in principle to that previously in effect for the production of high titer anti-A and anti B substances.

Rh-negative donors should of course be available through hospital lists for transfusions. It goes without saying that their standard blood groups must be established as well. Such lists cannot, however include women who have given birth to erythroblastic infants as their blood is apt to contain some anti Rh antibodies at all times.

In view of the comparative scarcity of de pendable anti-Rh typing serum to date as well as of the faurly well established scope of the Rh problem in medical practice, it is at present neither desirable nor necessary to type every patient routinely for this factor. It is however proper that typing for the Rh factor be done prior to transfusions, in any female patient before and within the child-bearing age, in all pregnant women, in any postmenopausal woman with a history of having borne erythroblastic infants, and in any individual, male or female, who is to receive multiple transfusions over an extended period.

If a hospital patient is found to be Rh-negative, and if there is a history of previous unexplained transfusion reactions or of erythroblastic progeny the blood should automatically be examined also for anti-Rh antibodies. If a patient is Rh positive but if there is clinical ground for suspicion of blood incompatibility—as for example in a pregnant woman with a history of ahnormal deliveriest—her blood as well as that of the husband may be sent to Dr Phillip Levine or to Dr Damond for Rh subtyping and Hr typing at least until such time as hospitals generally may have available the necessary testing materials for determining Rh subtypes, Hr bodies, etc. in their own behaviories.

If anti Rh antibodies are found in a pregnant woman the physician should be notified and may then consider prophylactic procedures such as premature induction of labor or cesarian section

The term abnormal deliveries should not include here monatrosities, such as a searcephalon, as both embryaingically and on the least of charact experience & lincompatible necessor be increasted for resident abstraction. This applies also to the relatively frequent mincurringes cuty in pregnancy In addition preparations should be made in advance of delivery for immediate checking of the infant s blood and clinical status with consideration of immediate transfusions of Rh negative blood, not from the mother. With such a treatment plan an anatomically normal-appearing infant, even if jaundiced at birth should recover completely. The chief risk is central nervous system damage from prolonged kernklerus ie jaundice of the cerebral basal nucles but such risk is slight if jaundice is not permitted to be come prolound or to persist over a long period.

If a woman whose Rh status has not been previously determined is delivered of an infant which is laundiced or edematous or unusually pale, and if the physician wishes to prove or rule out erythroblastosis due to a blood incompati bility without delay and with the fewest labora tory procedures, he should order a blood smear study on the baby ( differential count ) if this reveals erythroblastosis preparations for transfusions of nonmaternal Rh negative blood should automatically begin, with simultaneous determination of the baby's Rh and the mother's anti Rh status the latter tests to be done at that time chiefly to avoid the unlikely but possible accident of giving Rh negative and thus Hr-positive blood to an Rh negative baby carrying maternal anti-Hr antibodies. When possible the placenta should be saved in all such cases for pathologic study

There has been some published controversy as to the merits of giving erythroblastic infants Rh positive blood, on the assumption that the anti Rh antibodies transmitted by the mother to the infant might be more rapidly neutralized by the additional Rh-positive red cells. Even if this be granted (disregarding the clinical impression that such antibodies within the infant frequently are not free for complete neutralization at any one time, but are somehow 'bound' and are released only gradually to act on the infant a red cells) it should be kept in mind that the neu traizing of such antibodies is taking place within the living infant, not in a test tube and that it represents a wholesale destruction of red cells within the body without substitution of non affected red cells, so that an additional burden is placed on an already damaged liver as well as indirectly upon other tissues in the form, at least in part, of anemic anoxia. It would therefore seem more sound physiologically merely to re place the infant's own destroyed Rh-positive cells with indestructible Rh negative cells until the remaining maternal antibodies have diminished to the point of harmlessness, which will mevitably

# "INFLAMED AND INJURED TISSUES NEED REST

being placed upon the ambulatory treatment of fractures of the lower extremity and upon early rising after abdom inal operations after operations for hernia and after childbirth it may be worth while to recall some of the principles of Hunter of Hilton and of Hugh Owen Thomas and their insist ence upon the importance of rest in wound healing

The names of John Hunter and his older brother William are familiar to every medical student that of Hilton probably much less 50 John Hilton (1807–1878) began the study of medicine at Guys Hospital when only 17 received his diploma at the age of 21 and then entered the dissecting room as demonstrator of anatomy For 17 years he worked in the dissecting room and postmortem room before he was appointed at the age of 38 assistant surgeon to the hospital and lecturer on anato-

my In 1863 after the completion of a series of lectures before the Royal College of Sur geons he published these lectures in a small volume Rest and Pain¹ which exerted a profound influence both on his contemporaries and on succeeding generations of surgeons on no one more than on his admirer Hugh Owen Thomas His essential philosophy he expressed very clearly at the close of his four teenth lecture

By regarding this subject of physiological and mechanical Rest in what I concrive to be its proper professional light, the surgeon will be compelled to admit that he has no power to repair directly any in July I will induce him to acknowledge, in all hu mility that it is the prerogative of Neture alone to repair the waste of any structure. He will the reshire that his chief duty consists in ascertaining and removing those impediments which obstruct the ardernoving those impediments which obstruct the reparative process, or thwart the efforts of Nature, and thus enable her to restore the parts to their normal condition.

To secure the rest which he considered of fundamental importance in wound healing (as of course did John Hunter and many others before him) he constantly drew upon the extensive anatomical knowledge acquired during his long years of apprenticeship in the dissecting room. His emphasis upon the importance of pain as an indication both to diagnosis and to treatment, and his method of providing rest for inflamed tissue are pointedly brought out in his discussion on inflamed joints in Chapter VII

I may remind you that when a joint becomes in flamed it is painful and difficult of movement it becomes involuntarily fixed by Natures own process, thus securing comparative rest to the interior of the joint. Indeed we may lay it down as an axiom that Nature instinctively renders an inflamed joint comparatively fixed and flexed.

Rost and Pain. Course of Lectures on the Influence of Mechanical and Physiological Sec. in the Treatment of Accidents to Changle and Disposals Value of Pain. By and Sorgical Disposals, pain S. F.R.C.S. edited by W. H. C. be lat John Hiller, M. C. F.R.C.S. edited by W. H. C. Jacobson, M.A., M. Ch. (Ozne.) F.R.C.S. London; G. Bell and Son, Ltd., 1920.

He goes on to describe the innervation of joint and surrounding muscles that permits and brings about the rigid muscle contractions that immobilize and protect the affected joint. The obvious corollary is the careful splinting that provides a substitute and relief for the contracted muscles and permits the painful spasm to subside and still insure the needed of test.

The same principle of relief of painful and spastic muscle contraction resulting from in flammation of surrounding tissue is exempled field by many types of cases—fractured bone suppurating joints ostcomyelitis nerve in juries rectal and anal ulceration, etc. etc. A somewhat board application of the principle of rest that carries its own connectations is his of a patient with a chest injury (Lecture 1).

A physician, residing not very far from me had under his care a patient who had received a blow npon his chest by a fall upon the part and as he was, upon ma corest oy a sant open to pass.

atter several days, still suffering a good deal of pain in breathing the physician saked me to see him in reference to the possibility of fractured ribs. I could fand no fracture but I observed that the patient had ment to tractime but a observed that the partent and a most wortying wife. She was increasintly talking a mas worsyms with one was uncountry causes to him day and night, and there were continual contentions between them upon domestic affairs. I sag sessed to the physician that the sole cause of the Sexicu to the physician that the patient spain was, in all probability produced by the patient constantly moving the influed of brused soft parts by using his cheek and large in speaking. All I ree oy using no coest and using in speaking. In a recommended was that he should hold his tongue, and orannemen was that it amount may be suggested that his wife nave and come continuation. I requested that the would not say a world to him, but would provide him with a date and pencil so that he might write down all his desires. From that time he got quickly well

One believes that Weir Mitchell would have approved of this treatment.

Perhaps better known to the surgeon of today than Hilton is his follower and admirer that doughty little man with peaked cap and ever present eigerette to whom every worker in the field of bone and joint surgery is sogreatly indebted High Owen Thomas (1834-Thomas went still further than Hilton in his insistence on enforced uninterrupted and prolonged rest.

His message to the surgeons of his time was the they did not understand the meaning of the and rest. Hilton he said fixed a limb in a spint, and believed he had given it rest. Immobilisation be beld to be the first requisite but it must be appeal in to be the man required that it man or symmetric such a way that the diseased part was not compress. ed, nor the normal C culation of the lumb is arr ear interfered with All forms of plaster-spint accessrily exert an injurious pressure and for that research and several others he abandoned them at an early stage of his practice. Pressure he held, was a form of restlessness or irritation. If he applied a staff or clastic bandage to a diseased knee joint, so as to compress and surround it, he held that in so far as he lessened the movement of the joint be a seited repair but in so far as he compressed it he himdered repar Rest had to be continued without intermytee until all trace of unsoundness had disappeared loss the joint and then that point being reached the cure would be completed by the gradual return of natural voluntary movements.

Kenth in his delightful chapter on "The Principles and Practice of H. O Thomas in Menders of the Manned sees on to cite his application of the principle of rest in a condition with which we rarely connect the name o Thomas—obstruction of the horsel

"The treatment of the case I have selected for an example has been placed on record by his nepter Sir Robert Jones.

"I remember well how Mr Thomas called the reference tives together and told them he was going to make a fight for the patient a life. He used them to be loyal and to help him and to add to his personio. he threatened them with a coroner's inquest if they gate the patient anything without express permusion Above all things the patient was to have no mile that cardled and loaded the bowels with solids. Then the loot of the bed was to be elevated to lemen the pressure in the abdomen a morphia injection are given and nothing but ups of water with a fittle arrowroot. For the first few days he vasted the pr tient five or six times a day. Almost immediately the vomiting was reduced to about once in twenty-loss hours the patient became casy and stept, but the abdomen was tense. Twice he performed parameters an (for the relief of pressure) being careful sor to allow the trocar to remain in the intestine longer than a few minutes, for fear of a fistule. On the tramp fourth day at intervals, a very little fates was passed on the twenty-sixth large quantities, and

Manage of the Malmod, the Australia and Psychological Points of Edition in March 1982, April 1982, Apr

later in the day a few small scybalae. Again during the night a copous pultaceous motion and this again followed for three days by prodigious quantities of this facest fluid

From the method in which that case was treated we see that rest was to be applied with the meticu lous care and rigidity of a Calvinistic doctrine Rest was to be secured first by sedatives-to place the howel at ease and relieve nain the bowel was to be restrained from all manner of work by absolute star vation he declared he had never seen starvation cause death in a case of intestinal obstruction how ever prolonged. The bowel was not to be disturbed by any act whatsoever such as the giving of enemata or rectum ticking as he most unprofessionally phrased the practice. Nature, he said 'is late in working a relief and patience is needed. His critics said his treatment of intestinal obstruction was not new and modern surgeons will declare it to be bad. His medical critica, however were wrong opium and starvation had been often prescribed and employed in such cases rest had been enjoined but Thomas was the first to apply rigidly and completely the principle of rest as a logical system to such condi tions, and to carry it out in the form of enforced uninterrupted, and prolonged rest.

Many illustrations of the emphasis on rest in modern therapy can be quickly called to mind. The treatment of tuberculosis by rest of the body and rest of the involved lung is the very basis of modern therapy Wangensteen Miller and Abbott introduced an effective method of combatting intestinal obstruction that exemplifies the principles Thomas stressed so clearly. Orr applied the teachings of Hilton and Thomas to the care of ostcomvell tis and gave a new meaning to the words en forced uninterrupted and prolonged rest.' More recently Dragstedt has applied the prin ciple to the treatment of inflamed and ulcer ated gastric and duodenal mucosa by remov ing the irritating influence of excessive gastric secretion through division of the vagi

Accurate and painstaking as were the exper imental observations of Hunter the studies of Hunter and Huton in dissecting room and post mortem room and the clinical observations of all three men neither Hunter nor Hilton nor Thomas had the opportunity of following the process of wound healing by microscopic studies of tissue from experimentally produced

wounds It is of interest then to note that in reports of such studies by many workers (Harvey Howes Mason and Allen, and others) the lag period of wound healing is con stantly emphasized and the fact that during this initial period of from 4 to 6 days the strength of the wound depends solely upon the suture material used. Mason and Allen¹ have shown that in the case of sutured tendons the tendon ends become swollen soft, almost gel atmous and that tension applied during this early period can result only in cutting through of suture material and separation of tendon ends. Howes and Harvey¹ have stated

From this study one is able to say that fibroplasia starts abruptly at the fourth day and proceeds with decreasing velocity until a maximal strength for this phase of healing is reached around the twellth to the fourteenth day and that by the sixth approximately one third and by the eighth approximately two thirds of this strength is obtained. This of course, is readily checked against and correlates with surgical experience. This phase of fibroplasia has been studied in wounds of all tissues in which the normal tensile strength is greater than the maximum of the fibroplasia car ledentical in type.

The fact that at a later period during the process of healing physiologic tension and activity provide a helpful stimulus to sound healing of soft tissues of tendon and of bone was well recognized by Hunter, by Hilton and Thomas and again has been confirmed by many well controlled experimental studies. Until time has elapsed for fibroplasia to be gin-and its beginning will be influenced as Howes has stated 'by careful surmeal tech nic with the minimizing of infection and con tamination in the wound and with the inser tion of small amounts of suture material 'the 'injured and inflamed tissues need rest. It is obviously not the answer to every problem It is a principle of wide application and far reaching importance SUMNER L. KOCH

# THE SURGEON'S LIBRARY

# REVIEWS OF NEW BOOKS

E are happy to welcome the Journal of the History of Medicine and Allied Sciences' to the company of surgical and medical four nels. The motive for this journal and its purpose are so dearly set forth by Editor George Rosens introductory pages that we repeat a few sentences

"History is one of the most powerful driving forces in human development. Every situation that man has faced and every problem that he has had to solve have been the product of historical developments and processes.

10 uniconstant on own sweets to be capable of playing an intelligent role in sharing to be especied or pasying an intensigent rose in snaping our own civilization, we must have knowledge of the actions of the bast.

During the bast seventy nice actions of the medical profession pass. During the past seventy five years a mage part of the history of medicine.

sincerely believe that this trend has resulted in a serious loss for a profession which by implication still ecknowledges the importance of the historical approach each time it writes or speaks of the case approach come for this trend may be attributed to medical historians who were not always able to make modical history the living dy namic thing that we believe it to be. We do not want to cultivate medical history as a mere search for antiquities, as a kind of hunt for curios, but rather as a vital integral part of medicine.

No one would have agreed more whole heartedly with Dr Rosen than Otler Welch, Cushing and Cutter-men to whom the memories and achieve-Cutter-men to whom the neumans and while ments of the great doctors of the past were living and ments of the great of our heritage and our present day atte faments.

A partial list of the table of contents of the first number will give the reader a cine as to the scope of names was a second cause a cost as or the super of the new fournal. Some Galenic and animal sources the new youther come of Benjamin Water of Vessilus the London years of Benjamin Water house a note on William Blake and John Hunter pharmacopocias as witnesses of world history the postulated dentistry woodcuts. Bernardino Mon take de Monnerrate author of the first anatomy in Spanish medical education in 17th century England.

The editors of SURGERY GYRECOLOGY AND OR-After curious or Journal wishes to the new Journal and high hopes for its success

HE Manual of Surficial Anatomy by Tom Jones and Willard Shepard was prepared under the anapters of the Committee on Surgery of the

JOSEPHA OF THE HERRORY OF MERCENE AND ALLESS SERVEL. NOW THE LAND AND ALLESS SERVEL NEW AND ALLESS SERVEL NEW

Division of Medical Sciences of the National Research Council. It is one of a series developed to funds the medical departments of the United States Army and Navy with compact prescrition of necessary information in the field of military ar

The objectives are plainly set forth in the for word. According to Major General Kirk, in the tar gery of traums great demands are made upon the surgeon a knowledge of anatomy, in the treatment of traumatic injuries under the extrem condition of was a concise atlas of applied anatomy is required to permit "a rapid visual review of any part of the body and the proper surgical approaches to the

In a second foreword Vice Admiral McIntin commends the artists for the preparation of The drawings which for accuracy and simplicity may be considered unsurpassed. These comments and commendation record the chief characteristics and the successful nature of the Manual, they merely require elaboration.

The figures are arranged in the following order and with the indicated coverage in pages lead and neck (33 pages) thorax abdomen, and pelvis (40) apper extremity (49) lower extremity (50) The section on Illustrations is followed by a 55 page explanatory index, which is essentially a goosty It not merely lists the structures pictured but defines many of them and augments the attendant legends. Many of the figures are executed in sach a way that surgically important deep structures are projected (unally in color) in relation to super hcial, palpable, landmarks. For example, in purely anatomical pictures, cerebral ventrices, dari venous sinuses and tributary reins are shown is interrelationship and in their relationship to cerebrate Syri and to bones of the skull accessory at since and allyary glands in relationship to region of the face palmar synovial aboaths, to skeleton and to surface markings vessels and nerver, to bone of the extremities. In anatomicosurgical illustrations, which are the control of which are grouped in acts for the major divisions of the body the same very serviceable scheme is employed on even more ambitious scale. In the plate depicting performations, for example, the series begins with transverse section showing the austonical oute of approach to the heart this is followed by one recording skin and muscle inculous in reitne to the costal cartilages another to expose costal corrilage another to capacitation of the corrilage and heart with coronary vessels. Thoracotory translations and heart with coronary vessels. aymnathectomy laparotomy lambar sympathetic block arthrotomies for all major knints supraches

to all long bones commonly involved in fractures are illustrated with equal lingenuity. Ingenuity a hand maden economy is here an able supporter Surface landmarks, topographical succession in transected part, and structures scribilly encountered in the incisonal route are almost invariably shown in a angle plate of multiple figures with execully selected labelling of crucial elements and in a pattern of arrangement reflecting the best in artistic taste and the highest in pedagogic value

All drawings were done with the line technique. They are uniform, strikingly clear and invariably

crucel.

It is earnestly to be hoped that when the needs of the Army and Navy have been met, the book will be made available for regular commercial sale to medical schools. The undersigned would encourage his own students to purchase this excellent manual

DANNEY AVEN

THE two volumes entitled Clinical Cystoscopy by Lowram E. McCres can be recommended without reservation to everyone interested in urology The make-up of the books is exceptionally well done. The type is large and easy to read, the paper is of unusually good quality with a glossy surface that reproduces very well the photomicrospaphs, drawings, diagrams, pictures and actual color photographs. There are 66y illustrations of which 106 are in color

The first volume concerns the cystoscope its history and use in diagnostic procedures of the biadder and use in diagnostic procedures of the biadder and use in the seventeen chapters can be found reference to nearly everything that is known in modern urology The section on cystoscopic photography is proof of the author's creative genins in perfecting a camera that will take color pictures intravesically. The actual color photographs of the biadder mucosa both normal and deseated, are accurate and hie-like. Nothing like them can be found in any similar publication. This contribution to the specialty us the result of many years of patient labor and is definitely worth the effort.

The second volume as divided unto fifteen chapters, eleven of them are devoted to the kidney. Renai anomalies, function tests, injunes, infections, calcub, cytis and tumon are treated in an interesting and able manner. Chapter XXII discusses medical discusses of the kidney as subject not usually covered in a unological test. The last three chapters deal with unology in women and children and unological rontgenography. At the end of each volume is an excellent bibliography covering the subjects discussed in the respective chapters.

The author has been faithful in his intention to present a concise yet complete compendium of every disease observed or diagnosed by the cystoscope. He has presented his material in such a manner as to

CLIMICAL CHEOGODY: A TREATME OF CHEOGODY TRUNKS, DIAGNOST, PROCESURES, AND TREATMENT By Lawrida E. McCres, M.D. F.A.C.3. Philadelphia: F. A. Davis Co. 845-

make one feel that urology is an important field of medical endeavor. The accuracy of modern methods of diagnosis and treatment is clearly emphasized We feel that Dr. McCrea has made an important contribution to modern urological literature.

Ensuren Chowcev

THE interesting monograph entitled History of Surgical Aneithetia' by Thomas Keys has an introductory essay by Chauncy D Leake and a concluding chapter on the future of anesthesia by Nocl A. Gillespie. The excellent introductory comment of Chauncy Leake reviews his personal contacts with anesthesia. He stresses the lack of fundamental knowledge regarding the basic concepts of pain, and marvels at the accomplishments in the relief of pain regardless of the gaps in our knowledge still unbracked.

Thomas E Keys was reference librarian for the May Oclinic and, as a major with the medical corps was assigned to the Cleveland branch of the Army Medical Library These unusual contacts together with the author's keen historical perception have made possible this exciting human story of the

development of surgical anesthesia.

The work includes a revision of the five essays which were published in Anesthesiology revision of chronology and a selected list of references arranged.

by author and subject.

The author has made it his responsibility to correct many of the errors which have crept into the history of anesthesis and to try to present with an unbiased judgment, based on historiography the medical student an interesting picture of the drama on progress in anesthesis during the past roo years It will provide the anesthesist with a resumé and bibliography and the discerning anesthesiologist with an up-to-date compilation of many historical facts of anesthesis and related subjects. It can be highly recommended as a concise volume of factual information regarding the history of surgical anesthesis.

THE second edition of Nitrous Oxide-Oxygen Amerikasio' by Clement is enlarged by the addition of so pages and 22 engravings

The more important additions or changes in the second edition concern the nitrous-oxide theory of anesthesia, the technique of administration of nitrous-oxide oxygen the practical and applied physical oxyge of anesthesia, the mechanism and treatment of shock, the dangers of prolonged oxygen deficiency and details as to the use of the nasopharyngeal air way in dental practice. The discussion of shock as it concerns the anesthests has been markedly improved in this new edition. The section on physiology has been enlarged and improved through

THE HENORY OF SOURCEL A TERRELL. By Thomas E. Keys. New Jerk Scheman's, 245.

1 ork Scheman's, 245.

1 ork Scheman's, 245.

1 ork John Christian Aristylena, McKreso-Clerry, 1289

1 ork John Christian, 187 N. Christia, M. Jor M. C. (A.U.S.) ed ed.

Philosophia. Lee & Pringer 1845.

inclusion of recent advances in research. Considers. ble space has been devoted to a discussion of airways and particularly t endotracheal technique in anesthesia. As in the first edition there is an excellent review of the signs and symptoms which de velop under nitrous-oxide anesthesia and a helpful chapter devoted to the algusticance of cyanosis.

Full consideration has been given to preoperative medication and this subject is now set spart in a special section. Basic instructions for the administration of nitrous oxide-oxygen are not markedly

changed from those of the first edition.

The author emphasizes by repetition the need for preoperative medication for supervision of anesthesis by a well trained and experienced anesthetist for active co-operation of surreon with anesthetist and for an alert anesthetist who can recognise promptly the symptoms of impending shock and institute proper therapy MARY KARP

IT is always delightful, after an absence of months, to greet old and admired friends and when they appear in a jaunty new outfit and still sparkling with enthusiasm and helpful ideas our admiration is redoubled The new sixth edition of Homens Text book of Surgery! brings also an unwelcome reminder of the inexorable passage of time the distinguished author is now Clinical Professor of Surgery Emeritus nine of the twenty two original contributors have passed into the Great Beyond-all in the fifteen short years since the appearance of the first edition.

It is hardly necessary to point out again what a felicity of style and expression, what delightful glimpses of historical background and what a rich sense of humor Homans has added to a comprehensive grasp of surgical principles and technique to make this volume an outstanding contribution to the literature of surgery He has made the task of the surgical student a pleasant one and has broadened

his outlook in every direction.

It is always difficult in reading a new edition of so comprehensive a treatise to gauge accurately the changes and revisions that have been made. As Homans says in his preface 'the value of chemohas been affirmed the advanture of complete immobilization of wounded limbs has been supported and transfusion of abole has been found superior to the use of even the best of the blood substitutes. These statements indicate a few of the lines along which changes and additions have been made. Fortunately sufficient time has passed since the introduction of the railous mides and penicillin to give the author an opportanity to make considered statements concerning their indications and use (the sulfonamides) tend to starilize the blood stream but they do not be the bacterie in the initial lesion which still require surgical drainage' (p 73) the local use of such agents in abdominal wounds will probably be entirely abandoned (Allen) Intravenous ed-

ministration of the sulfonamides results in a rapid high concentration of these drugs in the peritoned Foreign body reactions occur in the abdominal cavity after local use of the less soluble members of the group" (p. 918) Penicillia is referred to frequently particularly in connection with spreading infection of cellular tissue, septic son throat, esteomyelitis, infections of the brain and meninges, of the ear and eye, of the pleural cavity

and of the genitourinary tract.

Blood vessel suture blast, the immersion sysdrome, the treatment of burns, the surgery of the sympathetic and parasympathetic system (unusually comprehensive) external fixation of fractured bones. the technique of skin grafting-are only a few of many subjects which have been enlarged upon or

included for the first time.

The bibliographical index-a distinctive feature of Homans Textbook-again directs the reader quickly and accurately to sources where he may find more detailed discussion and information of specific subjects. All in all the interested reader cannot fail to realise how well the whole field of sur gery has been covered and what a distinctive contribution Homans has made to surgical literature. Smerce L. Loca

#### BURNS

CHARLES C. LUND M.D., F.A.C.S. ROSS W GREEN M.D. F. H. LASKET TAYLOR, Ph.D., destruction of all the deep epithelial cells and

N comparison to the great economic npor tance of burns in all parts of the world in times of peace as shown for instance, by the more than 5 000 deaths per year in the United States alone acientific studies concerned with them have always been relatively small in number and relatively poorly supported. The present war with its lavish use of gasoline and oil as motive power and the use of bombing as a weapon has stimulated the Allies to mobilize as bonal resources and many scientists for comprehensive studies of the consequences of fire. This report will be concerned for the most part with the developments in Great Britain the British Dominions, and the United States. Nothing is known to the authors concerning any studies on burns in Germany and Japan or in their satellite or conquered countries during the 5 years since Belgium has been cut off from the Allied World DEFINITIONS

For many years the universal custom in the A Depth of burns United States and Canada and the preponderant custom in Great Britain has been to classify burns according to their depth into three categories as follows first degree simple ery thema second de gree, partial destruction of the skin but without

From the Boarn Anadements of the Stargical Services and the From the Boarn Anadements of the Stargical Services and the Medical Services (Associated Services) and Laboratory and Services (Associated Services) and the Health of the Stargical Services (Associated Services) and the Health of the t

third degree, destruction of the full thickness of the skin. In the French literature prior to the war the Dupuytren dassification was used by was the supply the desinition the definition most authors. In this classification the definition of first degree burns is the same Dupuytren s second and third degree burns correspond to superficial and deeper second degree burns as just classified and Dupuytren's fourth fifth and sixth degree burns correspond to the third degree just defined Converse and Robb-Smith have recently classified the depth of burns in a manner extremely useful to any one who is evaluating the estimated treatment. This classification divides results of treatment. the burns in such a way that the deep second de gree burns and mixed second and third degree burns, both of which types heal slowly under any treatment, are no longer tabulated with the more superficial second degree burns which heal ensity superness second degree value and they use a with almost any form of treatment. They use a name rather than a number to describe a burn name rather unit a number to describe a number of the rather names descriptions, and prognoses are compared in Table 1 with commonly accepted meanings of the degrees of the Dupaytren and American classifications. This excellent classification has been suggested so recently that it has not been used by other authors as yet. However there has been a widespread use by American authors of the subdivision of the second degree burn into superficial and deep second degree burns Admittedly the newly proposed class of mixed burns will contain only a small propor tion of the cases in any series, but these burns are a distinct and important entity. The authors of the present review will use this new classifica tion in order to avoid any confusion that may possibly arise by the use of either older classi-

heation

At the occurrence of the burn and for several weeks thereafter it is frequently not possible to estimate correctly the depth of the injury. Many small blebs, some broken and some intact, with an external core of plasma, visible pink corium, and minimal anhoutaneous edema indicate a dermal burn. A dry dead white brown or charred anpearance with beginning subcutaneous edema indicates a deep burn. The appearance of other burns is intermediate between those described and these burns cannot be classified until epitheliza tion or granulation have become evident. Dung wall and Patey and Scarff have attempted to solve this difficult problem. The former has observed his cases with ultraviolet light and a filter after intravenous sodium fluorescein injections. and the latter have studied serial microscopic sections of burns and also the naked eve appear ance after the application of Van Gieson's stain. Both these methods are promising but neither has been evaluated, as yet by other workers.

Until Dingwell sor Patry and Scariff's suggestions have been found to be widely applicable burns should not be classified until healing or epithelization is well under way. Most of the reent authors have been cognizant of this, but there are a few recent articles which indicate that the authors think they can estimate the depth of a burn when the burn is first seen. This is shown, for instance, by a statement that a given form of treatment has "prevented the burn becoming a deep burn.

#### B Area of burn

Although the proportionate area of akin burned has long been recognised as useful as a guide to the prognosts of burns, it has now become of even greater importance as a guide to treatment. On the first needs of a patient with a serious burn is adequate plasms therapy. After a close estimate of the area of the burn and of its proportion to the total area of akin has been made, a formula method to the serious cultimate the approximate amount of

plasma needed during the first day of treatment.

Such a formula will be presented later Long prior to its use for this purpose. Weidenfeld and Berkow (16) made studies directed toward simplifying the recording of and comparison of hurth. Both studied by actual measurement the surface areas of the parts and of the whole surface of many individuals of all ages. As a result of this work Berkow's table" is constantly in use in this country and Great Britain for the study of burns, and all recent important studies have used it. Both Weldenfeld and Berkow pointed out that the proportionate area of the parts of an individual vary widely between birth and adult life. Pack and Davis, Seeger and Wallace also pointed out this fact, but the ma jority of important publications that have stressed the use of Berkow's table have mentioned only his table for adults.

While in search of a suitable diagram and standards for the recording of burns in children, Lund and Browder found that Berkow's tables for adults and children, which have been perfectly satisfactory for work up to date, are oversumplified and contain certain errors that should, if possible be avoided in the more exact studies that are now being made in many chiles. The results of their study are seen in Figures 1 and 2, which are reproduced from their article. It should be noticed particularly that the area of the face makes up a relatively large proportion of the total skin area of infants when compared to the findings in adults, and is counterbalanced by the small area of the infant's thighs and legs. Also, the proportion of akm of all other parts is esentially unchanged from one age to another The area determined for the trunk is much smaller than the area assigned to it by Berkow

#### PATHOLOGY

#### A Local.

Burns either injure or kill cells. The cell membranes become abnormally permeable to various substances A very superficial burn will result in the injury of the most superficial cells but no cells will be killed. A deeper burn will result in the death of cells to a certain depth, and underlying these cells there will be injured but

The response to the mildest burn or the response to a more severe burn at the point in viable cells. depth where the burn is minimal is dilatation of the capillaries and the finer arterioles and venules with markedly increased blood flow through all of the three following a brief period of vaso-

In some mild first degree burns this is the only demonstrable result. In slightly more severe burns the capillary walls are injured and leak blood plasma into the ussues. At the same time other cell membranes leak and there is an abnormal exchange of cell constituents into the tissue spaces and of tissue fluid into the injured or dead cells. If the burn is deep enough red cells in the capillaries may be damaged or even rup-

Because of the leakage of plasma from the capillanes, the tissue spaces become distended tured immediately with fluid This fluid if near the surface, forms in blisters under the epidermis at first and after rupture of the blisters continues to pour out for more or less lengthy periods of time. The fluid that represents capillary leakage at deeper levels finds its way slowly into the lymphatic system (83) A result of this is greatly increased lymph flow from the area. Both the lymph and the bluster fluid coming from the burned area have long been known to be amiliar in composition to the plasma prior to the onset of infection (13

Presaman and his associates have recently restudied this problem and have found constant amounts of albumin and variable amounts of globulin in blister fluid Glenn Peterson and Drinker and Cope and Moore (45) have studied the flow pressure and composition of lymph after burns. The amounts of fluid that may be lost through into or under a burn are frequently large, as will be indicated later. It is also ex tremely important to remember that while the burned skin is permeable to plasma it is also permeable in the other direction. Absorption of various substances will be considered in detail

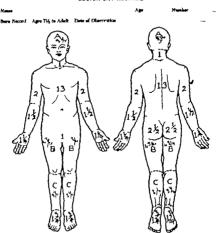

At once, after a burn repair processes start. When the damage is minimal the repair consists of the return of normal tone to the blood vessels the cessation of leakage, and the absorption of any fluid that is present in the tusue spaces. H

cells have been killed the dead cells are removed by lysis and phagocytosis. In case the burn is deep this process takes place only at the border between the living and the dead cells and the dead cells are sloughed off in masses or sheets. The intercellular collagen resists digestion more than the cells and the collagen fibers keep the slough attached until they are finally digested at the point of demarcation between the living and the dead parts of the fibers After the slough has separated repair of the denuded surface takes place by a new growth of epithelial cells from lalands of living cells, from the edges of the wound or by successful skin grafts. If the derma is destroyed and healing occurs by ingrowth from the edge, the repair may be quite imperfect because a very thin sheet of epithelium covers the dense connective tissue that results from the final contraction of the granulation tissue. Besides to being very thin this scar epithelnum is poorly nourshed and poorly attached to its base. The repair process may be delayed as a result of local treatment, of infection or of various deficiencies, such as those of iron protein or vitamins, but cannot be sumulated to heal except by creating optimal conditions so that there is no interference with cell division and cell maturation

Pathology of red blood cells Inevitably when sufficient heat penetrates to a depth in the tissue where there are capillaries, some red blood cells are injured. In vitro studies have shown that thermal injury of these cells occurs between 52 degrees and 65 degrees C. (167) Lysus frees the hemoglobin which is in the

The occurrence of hemoglobinemia and hemoglobinura after severe burns has long been known guomma and avery serious burn. In general, the former is seen only in deep burns of to per cent or more of the body area and the latter in such burns of 30 per cent area or more Hemoglobinemia when it occurs, is found to be most severe immediately after the burn and to decrease gradually during the first 24 to 72 hours. A long duration of hemoglobinemia in the plasma does not occur following burns. Hemoglobin does not appear in recognizable quantity in the urine unless it is present in large amounts in the plasma Its duration in the urine depends on its duration in the plasma. The hemoglobin in the plasma and the urine has been shown to be for the most part oxyhemoglobin mixed with traces of methemoglobin (167) There is no evidence that burns ever release any form of myohemoglobin such as is found after crush injuries."

Shen Ham, and Fleming have confirmed the work of Spiegler and others who found that the blood of the burned patient with hemoglobinemas contained many abnormal red cells, such as fragmostic cells and aphenocytes with an in creased camotic fragility. No hemolysis or agglutuma are found (48). Hemoglobinemia and bemoglobinemia are discussed with the kidney.

#### C Blood plateless

In very severe burns thrombocytopenis severe degree occurs. MacDonald and her sociates have ahown that the platelet count decrease to less than 95,000 within 76 burns murry and the level may remain lew days. This confirms older work of Sairiolf is to confirm that of Welf and Locke

Leucocytosis appearing immediately after the D II hate blood cells injury and continuing for variable lengths of time has long been known as a constant finding in nearly every burn of moderate or severe extent. The early leucocytosis is usually directly propor floral to the severity of the burn Later the leucocytosis varies directly with other evidences

of infection such as fever In a few cases of severe burns a leucopenia or relative leucopenia has been observed between the first and the sixth days. During the early leucocytosis or leucopenia the differential white blood count may show an increased proportion of nonfilamented leucocytes and other degenerative changes in the leucocytes, and the presence of myelocytes and the abscence of cosmonfuls. Van Duyn has recently expressed the courion that these degenerative changes are the result of a torre infers to these cells and that this proves that there is toxemia associated with hums that cannot be accounted for by injury, hemoconcentration or infection. In his oninion this toxemb is caused by some substance absorbed from the humed area

#### F Frank function

Impairment of renal function as evidenced by anuria olemnia, and agotemia is a con nicuous feature in the early course of nationts with severe burns. Albumin hemoclobin and casts are frequently found in the unne of these nationts. while large numbers of white or red blood cells are rare. Reversible azotemia, a sociated with transient objeurs occurs frequently even in lums of only moderate severity. This phenome non is similar to that found following shock of any type and is presumably due to a decreased blood flow through the kidney during shock. The blood flow through the kidney may be decreased to one-twentieth of the normal at a time when the erneral blood flow is reduced only to one-half (111) This is true particularly in hum shock in which the vasoconstriction at any given peripheral I lood pressure seems to be almificantly ereater than in other types of sbock. Van Slyke has shown that a severe reduction in renal blood flow for many bours without reduction in the flow to the rest of the body may be followed by anuria an I death of animals

It has also been suggested that the kidner failure of burns is caused by the hemoglobin that is excreted in some cases (10). This is successful by the histological changes in the kidney which are similar to the changes in nationts with hemoelobinum due to causes other than burns. The principal histolysical changes are the presence of pigmented (bemorlob n) casts, poppirmented epithelul ca a a d accross of the tubules At automy on patients who unvived more than to bours beginning re-creation of the tubular enithelium is also seen (-6)

Although it is well establis of that intra vascular temolysis from a lariety of causes is free ently I Bowel by failure of kainer function the receasi m of this action and the causaine arms of arms in the bemolved Lood re-It that or not been determined. tata ! ! raux

414

771

is involved, that is that these seems much ann toxic to or only toxic to a killery with an inpaired flow of blood

The problem of the taxicity of hemolyzed bar is intimately linked with the overtion a city alkalmization of the print prevents renal dame-The first urine of nationts with severe lamy is almost invariably strongly acid and immet . . administration of alkali to the nation has less recommended. The purpose of this alla aretion is to present precipitation of the products of the destroyed red cells in the renal tubales is the presence of an acid urine (10). In most rates a hemoelohinemia and hemoelohinuna, when fort observed have already been present for at least an hour before this examination is made or be fore any alkalinization is not ible Conserned the there are no actual data available as to the prophylactic value of this treatment in human te ings and no experiments with animals are known. Although no evidence for or against the raire of alkalinization on entry for this nursose has leen found after careful studies at the Boston City Hospital and the point is still controvenul, we feel that it should still be used. Alkali treatment of burns for other nurnoses is not new but has re cently been brought into great promuter to Resenthal and by For. It will be discussed further under shock.

#### F Pathelogy of the liver

From the time of Bardeen's work there have been reports of liver necrosis in burns. Barkers described a diffuse injury to all the inver er"s Following Wilson and his coworker's report in 1938 there began to be many reports of a di ferent type of infury characterized by fall re cross of the central cells of the lobules a. I by marked polymorphonuclear leurocytic mf traters of the necrotic areas. Wilson queried at that time whether the then popular tannic acid treat ment had some causal relationship to this cha. In 1941 Wells Humphrey and Coll, by dincal and experimental work, definitely a owel that this peculiar necrosis was due to tarel, and poisoning This has been confirmed by others ( t 03) It has also been slown that the me of c application of the tannic acid informers L. amount of its absorption and therefore to or gree of liver injury (93) The forms of treatment that induce slow tanning such as tame, and baths or tannic acul felles a 1 or top 1 are more dangerous than rapid tan and w 5 ta. ) acid and Ever nitrate solut 'rs (te g 155) However as Lee pos 15 out 1 ere 15 liveragens, encountered in tree a ment

acid is used but very few cases have been reported in which bland ontments, saline solution or dry dressings have been used (63, 133, 176) A case of marked central necrosis of the liver has been seen when triple dye was used for the surface

Late liver damage as evidenced by jaundice and decreased prothrombin concentration from 2 treatment (115) to 6 months after injury has been seen in a num ber of patients who have received human plasma or whole blood (114) All of these patients recovered. Clinically these cases are similar to and probably identical with cases of homologous serum seundlee which are due to the transmission of a virus of infectious hepatitis in serum plasma or blood (172)

### G Pathology of the kidney

Scattered pathological studies of the kidney in patients dying of burns have been made (131 184 194) the most recent being a report by Goodpastor et al., who found a close correlation between clinical and laboratory evidence of kid ney dynunction, extent of deep burn seventy of shock, hemoglobinuma, and renal morphologic changes at postmortem. The most consistent anatomical changes were the following on microscopic examination the glomeruli were normal and the tubules showed varying degrees of necrosis affecting principally the ascending and descending portions of the loops of Henke. Pigmented casts in the tubules were a constant finding in these Cases. These casts have been considered to be de rived from the breakdown of red cells, although direct proof of this is lacking Some support to this conception is lent by the demonstration of hemoglobin, oxylemoglobin, and methemoglobin in the blood and urine of all severely burned pa tients. In addition casts composed of desquamated tubular epithelial cells have been found in most of the same cases. Evidence of regenera tion of tubular epithelium was seen in most of the patients in this class who survived more than

In contrast with the marked microscopic abnormalities, the findings of gross emminations 72 bours. were essentially normal In a few cases the kidneys were swollen the cortices pale, and the meduliae dark red, presenting prominent black, brown or purple red streaks converging toward the papillae. These streaks corresponded to the

It is quite apparent from the description that tubules filled with pigment casts. the renal changes are similar to those following hemolytic blood translusion reactions, traumatic shock crush injury and hemolytic sulfonamide

Goodpastor et al believe that the important ethologic factors of injury to the kidney in burns are the presence of marked hemoglobinema hemoglobinuria and severe shock.

## Pathology of the gastrointestinal tract

The occurrence of ulceration of the intestinal tract following burns has been recognized for over 100 years Curling directed special attention to this subject in 1842 Harkins (87) has recently reviewed the reported cases The occurrence of reviewed the reported cases the occurrence of gastrointestural ulceration following burns is more common that coincidence would allow A severe third degree burn often of a sloughing septic type is most apt to result in such an ulcera tion A decreased incidence of this complication may come from a more aseptic handling of burns. The only other therapeutic considerations are the realization of the possibility of these ulcers and institution of the proper medical or surgical treat ment of them as is indicated. Up to the present time, no acute ulcer following burns has been treated surgically

Children and females are more often affected but this may be because they are more frequently burned. The symptoms of such an ulcer may be of rapid onset and include epigastric pain melena and hematemesis. The average length of life in ninety four cases with necropsy collected

from the literature was 15.4 days. The ulcer involved the duodenum alone in seventy-one cases, the stomach alone in sixteen cases, and both organs in five cases was single fifty seven times and multiple thirty four times Hemorrhage was twice as apt to be a Istal factor as perforation and the pancreas was often exposed and the pancreaticoduodenal ar Thirteen reports of gastrointestinal ulceration with recovery are also mentioned by

The etiology of the ulcers has not been deter mined. Various theories involving nervous in fectious toxic, and embolic factors have been Harkins. suggested (87) Necheles and Olsen studied the gastrointestinal secretions following burns, as the salivary pancreatic, and biliary outputs were sauvary pancreauc, and onney outputs were considerably diminished. The gastric secretions however were increased by several hundred per cent with an associated increase in gratric motility These writers believe that these obser vations bring forth 'new light on the problem of

Actual ulceration of the gastrointestinal tract has been seen only once in the Boston City Hos-Curling s ulcer" pital series of 60 recent autopsies Therefore, Levensonetal (rrs) think that it is a rare complica

tion must the present modes of treatment. However, the same observers as well as Mallors and Brackles, have confirmed the older observations of congestion of and diffuse hemorthage from the upper gastromitectical tract in human beings. They made these findings only in those patients with exten the burns and severe shock. In Leverson's series there were 6 instances of these findings tot as mentioned above only a Cutling source Similar changes have been found more frequently in experimental animal. particularly the doe and call (75). These changes were as centuated by preburn and postburn heparinara tion of the animals (74).

#### I Pertus wy tract

Up to 1012 injury of the respiratory tract had occasionally been reported as a complication of burns. At that time injury of the respiratory tract a umed great prominence since the masorts of the victims of a tire at a Boston night club (The Coccanut Crove) in which about 500 people lost their lives, had suffered damage to their respirators tracts. The clinical and a ray a precis of these cases will be discussed later Pathological examination (110) revealed that the respiratory damage was essentially that of a laryngotracheobroachitis. Three patients who were dead on arrival at the hospital were examined at autotos, and all showed an intense but mennecrotizing bemorrhagic tracheitis and bronchitis, and presented heavy voluminous lun- from the cut surfaces of which fluid in large amounts could be expressed. Microscopic examination confirmed the presence of scute pul monary edema and demonstrated in the upper tract-cobronchial tree a sembemorphagic exula tion without significant leucocytic infiltration (110)

In in Invituals who deal after varying periods of time in the brightal, (in 12 days) severe ne crotting tracheolemachiti was found with the fination of a peur odg hiberitic membrane Mary of the reconstoning issuese were occlased by the possiblementane and viscal mu of an august consist around the armonant lamage consist of chiefly of corner yets on one and scattered areas of all exists the emphasemanches the fitter of the saph servers after a surressist of their treesagh servers after a surressist of the treesagh servers after the result of the saph servers.

A few case resulted from the inhalation of smoke form a fer involving nolly a bed.

#### 1 Idrosali

Neiskotten stated in 1917 that the most preminent and characteristic necropsy finders in pa tients with burns were chances in the a re-ulplands. He described swelling realers and periadrenal edema with hemorrhage in all raws of more than 24 hours duration. Microscopics 7 there was necrosis of the cortical cells. Since then others (17-142-79) have reported similar for in rein some but by no means all, burn su, orner. The most recent report is that of Mallon a f Brickles who found focal necrosis of the alteral gland in a cases in which death occurred in Iron ? to a days after the burn. They mentheed and ting of the cords of the outer portion of the certes with accumulation of serous exudate in the spart produced, pyknotic nuclei acidophilu necresi el the adrenal cells, and infiltration with pomorphonuclear cells.

The finding of depleted cortical lipsob partial lath, cholesterol, following burns has been recently confirmed by Sayers et al. who state that lo burns the a brenal glands are stimulated to rehavious by the a frenotropic borno e of t anterior pituitary lobe. Harkans (50) has stated simulat findings and conclusions.

#### K. Spleen and lymph notes

Barleten described seeking and near sin the 1 mphord nodules of the lymph podes perpend imphord tissue and spaces with the construction of the management of the found that his legrees of known feet at the found that his legrees of known feet with found only in children day a which is the found that his legrees of known feet with found only in children day a which is the found that his legrees of known feet with found only in children day a which is a force than manural known feet in the found of a tingle subject beyond a core to

Baker raises the questions whether the karvor rhems is pre-existent to the burn ie a normal finding in children and whether its absence later is not the abnormal feature. Further studies are required to clarify this point.

#### L. Heart.

Kayashima found that after experimental burns in rabbits, electrocardiograms were abnormal. The waves were low in amplitude, the T wave was flattened out, and the ventricular complex tended to be monophasic. Similar changes were observed by the same author in 12 Naval canalities (from 21 to 37 years of age) with from 11 to 20 per cent body surface burns who recovered. Histologically interstitial myocarditis with perivascular infiltration of leucocytes was observed in the rabbits. Buts and Hartman reported 2 cases in human beings (among 6 autopsies) of microscopic fragmentation of the myocar dal muscle fibers.

#### M Pathology of the central nervous system.

Delirum, stupor coma convulsions, hyper pyrexia, and Chevne-Stokes respiration signs which may indicate central nervous system in jury have been described following extensive burns. There have been very menger reports on the pathological changes of the nervous system. Wilson in reporting on a series of extensive scalds and burns mentioned toxic damage in the brain in occasional cases but did not localize the lesions. Pack quoted Crile as saying that the central nervous system injury was seen only as a result of profound shock. Mallory and Brickley reported cortical ganglion necrosis in 1 of the Cocoanut Grove cases, but the patient had suffered from severe anoxia in addition to external burn. She had evidence of carbon monoxide poisoning shock, and severe respiratory injury the first two causing anoxia from the start and the latter causing it later

Walker and Shenkin have reported on 6 pattents who were observed to due of sudden respiratory arrest. All their patients showed essentially the same signs chinically disorientation and mank or stupor with abrupt faulture of respiration but without obstruction of the airway Five of the patients died about the fourth day but the sixth died on the sixty second day. Post mortem examination showed cerebral edema with evidence of marked increased intracranial pressure including widening of the gyri narrowing of the suict, hermation of the temporal uncus through the incisura of the tentorium and hermation of the cerebrilar ton its fine the foramen

magnum. There were marked changes in the smaller blood vessels consisting of degenerative changes of the endothelial lunng with occasional breaks and perivascular petechal extravastions. The ganglion cells throughout the brain showed toxic degeneration, but the most striking changes were in the cortex and hypothalamus particularly in the latter

According to these authors the pathogenesis of these lesions is not clear. Anoxia or the presence of a circulating toxin (32) as suggested by Christophe must be considered. He showed by cross circulation experiments that changes occurred in the paratuberian centers especially at the para ventricular and supraoptic regions of the anterior thalamus. It should be borne in mind however. that Walker and Shenkin's patients showed generalized edema as well as cerebral edema, and It is possible that the cerebral changes are a secondary effect Many additional studies are needed to clarify these points. Unfortunately the few autonsies that have been done on burned patients have seldom included an examination of the head

#### METABOLIC CHANGES IN BURNS

#### A Electrolyte metabolism

The findings of a decrease in plasma chloride concentration in the first few days following an extensive burn first reported by Davidson in 1926 has since been confirmed by a number of workers (52 180 163 179 70 44, 171). These later studies have also demonstrated a decrease in serim sodium concentration and a decrease in urinary sodium and chloride excretions. Fox and keaton Cope (44) and Hirshield (92), using midioactive sodium have confirmed Underhill's Rudier's and Lowdon's findings that much of the lost sodium chloride went into the burned area.

A shift of some sodium into the injured cells in the burned area with a shift from the injured cells of an equivalent amount of potassium has been demonstrated by Fox and keaton and Tabor and his associates (170) The actual rise in circulating plasma potassium concentration is small and well below the toxic range for normal animals (196) However, Tabor (171) has shown that the shocked animal is considerably, more sensitive to rises in plasma potassium concentration than the normal animal.

#### B Autrogen metabolism

Cuthbertson first noticed in 1930 that patients with fractures excreted abnormally large amounts of nitrogen in the urine for weeks after the injury and that this was associated with a loss of weight

and muscle wasting Lucido n ted a similar process in a burned patient. His observations were amplified on large numbers of nationts in a group at the Boston City Hospital (114) during the last a years. It was found that all severe liums that were neither anunc nor too severely eliguric had a birb output of nitrogen in the unne donne the first a weeks and that in a few cases this output continued for many months. Steady loves of from 25 to 30 grams of nitrogen per day have been observed frequently, and on an occasional day the los mas be as high as ac erams. This early increase in umnary nitrogen excretion has also been reported following any acute trauma poisoning or infection (25 50 00 124) The cause of the exces ne altrogen excre tion has not been finally determined. There may be more than one precipitating factor. Associated with the high urine excretion is an early high contratein attroven level in the blood which is the result not only of a decrease in kidney function (transient or permanent) but also of an increased production of nonprotein nitrogen products (16) Clearing of the increased nonprotein pitrogen accounted for only a small fraction of the total urinary nitrogen in rease. In severely homed na tients there is lestruction of large amounts of tusue followed by autolysis and almoration of its products. There is also the possibility that the protein catabolism i in reased by the absorption of specific substances from the burned areas (110) and from the so-talled toxic deceneration of r rotein" associated with fever and infection (140) Increased gluconcoveres may be responsible for 1 art of the mercaned protein breakdown. Browne postulates an in reased production of S hor mone by the a frenal cortex and simultaneously a decreased production of \" bormone which re sults in an increased protein breakdown as a sten in the I mate n of ele one. In any event it has been recently bown that marked abnormalities of the carla hydrate metala him do occur in severely burrel animal (saran I burnan beings (176) and are are used a th h perglycemus lictacefemus and a lowered cart in du sale combinue power This will be a credit more detail later

eath increased nitrogen, both in the bac 1 a, urine is due in some cases to the presenced; normal mounts of residual nitrogen," in a tion to an increase of normal rabs ances seeing ureal creating and amino acide, 1 a are found in the normal blood and nine. Safety, tory chemical characterization of the connected has not been made.

At the same time that from 25 to 32 grant of nitrozen are being excreted in the unite and the tional 30 to 40 grams of nitrogen may be but in a the surface of the burn daily (178 as 48) 5 4 important losses of pitropen from the surface are commonly seen only in extensive deep barns be in these the losses may continue over long remoti of time. Early after superficial burns there is a large outpouring of plasmalike fluid through Le skin. This contains a high proportion of pro ru Later during the sloughing and granulators stages of deeper burns there is a steady and cosulerable loss of protein in the form of puruent material from the surface. The amount of bu varies directly with the area involved. There losses continue until healing is compare & h losses from surfaces and wounds have not in the pa t been considered in calculating conventional nitrogen halances, and it must be realized that errors of great magnitude may be introduced by such studies unless this factor is considered.

While the large quantities of nitrogen are 1 or 1 lost in the urine and in the dramage from the wounds of such patients, the protein irtile is likely to be greatly reduced by reason of Pic. anorexia and poor gastrointestinal function. Th negative nitrogen balance occurring under these conditions may have serious effects in a few days in the patient with already depleted body per raand in a few weeks in a patient with excellent protem autrition. This is reflected in the dree ?ment of a progressive hypoproteinemia. Tele v an extremely serious metabolic sign. During the first week following a burn a transitory by oreteinemia may be present it is d e to st'is el water electrolyte and protein from the burst stream into the subcutaneous it see er ert. a ? This early hypopenteinemia is without nutrick all significance On the other hand, a cor bandte in plasma proteins after the first week is a s gret marked tis ne protein deprivation. #### C Cartoled are marketime

Hypergl remu Isctacefemia a. Hwerrel caton dioxele combining power are frequency from in human beings and animals following burns (sa. 180, 127) The extent and duration of the changes in these blood constituents are roughly proportional to the severity of the burn Clark and Rossiter working with rats and Greenwald and Ellasberg (70) working with rabbits found decreases in the muscle glycogen following burns, Similar determinations have not been made in human beings. Any increase in lactic acid produc tion due to an increase in the rate of muscle giycogenolysis may result in hyperglycemia through conversion of the lactic acid to glycogen and glucose in the liver. The rate of lactic acid formation following burns is, however apparently greater than the liver can handle, resulting in iactacidemia as well as hyperglycemia. In addition to an increased glycogenolysis, another possible source of the extra blood sugar is glucose de-

nved from protein (24) Many investigators have emphasized the role of the adrenal glands in the production of abnormal ities in the carbohydrate metabolism in burns. Hartman (04) has demonstrated an early in creased adrenalin production Browne and Cope et al (47) found increased 17 ketosterold excretion in the first few days following burns, which was followed by a decrease below normal values Numerous pathological studies, as already men tioned have revealed adrenocortical hypertrophy and marked depletion of lipoids. Adrenalectomy was found by Slocum and Lightbody to prevent the lactacidemia but not the hyperglycemia in burned rabbits, while Clark and Rossiter found that neither the lactacidemia nor the hyper glycemia was abolished. It appears that although the adrenal glands may play an important role in the production of abnormalities in carbohy drate metabolism following burns, the entire picture cannot be explained on this basis and indeed the effect of the adrenal glands may be of

#### a secondary nature D. Vitamins

Increased demands for vitamins in burns have been suspected for some time by analogy with studies showing increased needs for vitamins in other diseases (81) Emphrically vitamin preparations such as cod liver oil have been used locally (121) and only for many years in the treatment of burns. Very few assays of vitamins in the blood urine, or tissues to determine the actual requirements in burns have been made

In 1937 Usbekov studied the content of ascorbic acid in the adrenal glands and in the liver of guinea pigs that were kept on various diets before and after burning He found a progressive

fall in the ascorbic acid level in these organs following burns of from 45 to 50 square centimeters of akin. This decrease occurred in all animals no matter whether their diets were high or low in ascorbic acid. The pigs on partially deficient diets showed indolent healing and 'poor' granulation tissue and lost much weight. The animals on better duets lost less weight and had 'better' granulation.

Lam reported low plasma ascorbic acid con centrations in a few patients with extensive burns. Clark and Rossiter and Harkins (00) reported a decrease in adrenocortical ascorbic acid concentration following burns in rabbits, rats, and guinea pigs, Lund, Taylor Johnson and associ ates have studied plasma ascorbic acid concen trations and urmary excretions of ascorbic acid thiamin, ribofiavin, and n methyl nicotmamide in man in the acute and chronic stages of burns They have found that in patients with severe burns on high protein diets supplemented with two or three times the National Research Council daily allowances of these vitamins recommended for healthy individuals (18) the plasma level of ascorbic acid and the unnary excretions of all four vitamins may decrease to very small quantities. Even with small burns the patient on a nonsupplemented house diet may do the same thing. In patients with consistently low plasma and urine ascorbic acid levels the granulation tissue is absent or edematous akin grafts fail and epitheliza tion is delayed Burned patients with low excre tions of B vitamins may have poor appetites, poor bowel function asthenia and poor morale The extra needs for vitamins commence with the burn and remain until healing is complete. In general the extra amounts needed to prevent depletion parallel the area of unhealed burn. Whether it is desirable to try to maintain fully saturated levels of ascorbic acid in the blood and the excretion of appreciable quantities of all four vitamins in the urine is not known. The mainte nance of such levels will, in very severe cases entall the administration of up to 2.0 grams of ascorbic acid, 50 milligrams of thiamin 50 milli grams of riboflavm and 500 milligrams of niacina mide. Comparable studies on any of the fat soluble vitamins and on all other water soluble vitamins have not been made 1

#### BURN SHOCK

Burn shock may be defined as a condition of low blood plasma volume, low cardiac output, low blood pressure and increased peripheral reface the was written Andreas and associates have reported studied for it desired conveniences. In other and have found as increased as

a tance to blood flow. The four factors that have for a long time been considered important a causes of burn shock are loss of circulating o tema toxic substances in the blood pain, and co 1. The two former are now considered to be of prime importance an I the two latter to be at most of minor contributing influence. Shock following a lum may be expected in cases of normal adult with a burned area of 15 per cent or ereater and in cases of feeble adults or children with a humed area of 8 per cent or ereater. As burn shock a frequently fatal if untreated it is a ut ject of great importance and will be considered in some detail. Until recent effective methods of treatment became available most nationts who hed, died in shock. Now they die later

#### Canter

t Loss of circulating plasma. The most im portant cause of burn, book in most cases is the los of plasma from the circulation into the tis ues of the burned area and through the burned area That such losses are large and that the plasma volume is creatly reduced have been postulated for many years because of the severe degree of concentration of red blood cells that has been observed. The first direct quantitative mea ure ment of the reduction of blood volume in burned animals in shork was made by Johnson and Balock in 1911 They from I that the amount of I look that could be removed from such an animal before death was ery small. The amount they named the beeding oforce. Chart No 1 illustrates the course of the houtocrit and hemoglobin charges in a patient at ha dermal burn of the hand, and face only ( of the body area) who at no time decerned of a shock

As may be seen from the chart, tie bin hematocrit and hemoglobin a hour after it in were alrea is markedly elevated which dearstrated that the fluid loss may be very marked a first. During the first day the rationt recencile parenteral flui le His otal intake was al erra. his urine output uso cubic centimeters. At u.e. end of 24 hours his hematocrit at I hemoel. had men still further reaching by per cent a. 135 per cent respectively. During this time there was very little external course of para. but an increase in the amount of subcularies edema of the face and neck was rubble. Dutiet the second day the edema begin to subside a simultaneously the hemoglobin and hematicar levels began to fall. By the fifth day the of "a had disappeared and the bematocrit and becoglobin had returned to normal. During this ! the plasma nonprotein nitrogen concentration in mained normal while the total pro em 2 ! albumin concentrations showed slight falls

Comparing the reduction in bood roller to other possible causes of burn shock Ros : or his recently concluded. It is therefore probable that these enormous losses of planea from the bloodstream will initiate shock. I firm see I this prove but one of a number of initiating the tors it is one of himmense importance and easily which justifies vigorous countering uses.

2 Toxins. The literature e meern factor or factors in hum shock is vol me me! very controversul, although few authors have been positive in their denial of such a perc. contributing factor Christophe by some imp ingenious cross circulation experiments in dep howed that circulating toxics injured the lea an I fed to death This he described a "Ir calearn leath." Certainly some of the cle- a. hannes arrocated with these death in lyate the probability that the logs were le o.k at " time prior to death although he 'es out mal per L'e mention of it Another demer rat " burn shock apparently produced w c) by t a fa tors and una sociated with putera less has been made very revently on rats by I'r grate ar Ilus a sociates. He found that rate wh haver mu J burred at ,5 derrei C for 10 8 m in bud hims dese wed mar of sin over with conversite heat work built d Ar a hock On the other back as where sing to I for a near sever I amal at 17

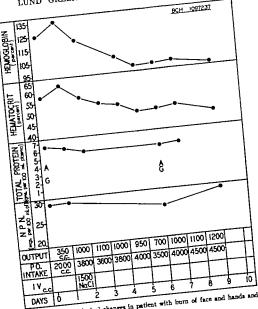

Chart r Hematological changes in patient with burn of face and hands and without shock.

degrees C. for from 2 to 3 minutes died in shock without visible edema and exhibited insufficient local fluid loss to account for death. Similar re sults were obtained when larger areas of the body were severely burned for 10 seconds. These au thors concluded. It is therefore apparent that there are at least two mechanisms capable of producing shock one due to local fluid loss and the other due to some unknown factor

Another important contribution to our knowledge concerning toxins has been made by Perl man, Glenn and Kaufman who described a large amount of a new globulin fraction in the lymph collected directly from the burned area in calves. This globulin may represent a toxin

Rawlinson and Kellaway have found great increases in phosphatase phosphate proteolytic

enzymes esternse, and catalase from heated liver slices as the temperature approached 50 degrees Kellaway and Rawlinson studied tissue in jury by heat in isolated limb preparations. From the perfused hind limbs of guinea pigs and the forelimbs of cats histamine was liberated between 45 degrees and 50 degrees C. In the early hours of perfusion a substance relaxing smooth muscle which inhibited the stimulating effect of histamme was present in the perfusate. No active adenyl compounds could be detected between 37 5 degrees and 50 degrees C. but cardiodepressant activity was found between 42 degrees and 50 degrees C. This was also present in the subcutaneous edema. It was heat stable and was not diminished by incubation with cat muscle or not duminished by incubation with the industry of cat liver extracts. The hydrogen ion concentra

tion of the perfusate showed its greatest increase between 44 degrees and 45 degrees C. The small output of inorganic phosphates between 37 5 de grees to 41 degrees C. was markedly increased at the higher temperatures. Alkaline phosphatase, lipase, and proteolytic enzymes were also set free above 41 degrees C. These authors concluded The demonstration that lipase and proteolytic enzymes were set free from the perfused hind limb of the cat above 41 degrees C. gives color to the possibility that toric products may be formed by ensymatic activity in the tissue spaces. Proteolytic enzymes in lymph from the burned area have also been reported by Zamecnik et al

Rose and Browne have found very high blood histamine levels immediately after the burn. The amount of histamine present decreases rapidly as toxemia develops. These findings are not altered by the administration of sufficient plasma to prevent hemoconcentration. There is a correlation between the degree of injury and the decrease of the histamine content of the blood-Thus, the most marked decrease has been noted from 12 to 16 hours before death. Similar findings have been observed in cases of fatal shock.

Beloff and Peters have found a proteinsse that is liberated from burned skin that they discuss in relation to "burn toxin theones," but they do not

claim that it causes burn shock.

Muus and Hardenbergh have observed that the oxygen consumption of normal rat liver slices is increased when measured in lymph from the burned legs of calves or one dog as mediums. The increase over similar measurements in normal lymph was as great as 41 per cent. When serum was collected after burning a smaller increase was found. In this connection Taylor and his associates (176) have found an increase in the basal metabolic rate in severely burned nationts. The rise was greater than could be accounted for by the fever that was present at the time of the test.

Aub (7) has found that the fluid obtained from within the sheath of a muscle that has been made ischemic by the interruption of its circulation produces shock when injected into normal does. Exotoxins produced by organisms of the bacillus welchi group were found in this fluid. These bacilli were found to be normal inhabitants of normal dog muscle. Under the anserobic conditions of these experiments the number of organ isms and the amount of toxins produced are greatly increased. The toxic effect of this finle is nullified if suitable antitoxin is mixed with the fluid, or injected separately but simultaneously into the dog Animals immunized with toxolds are resistant.

Chalkoff and his associates have found that fluid expressed from the skin and subcutaneous through of burned areas in dogs is toxic to pata. Gram positive anaerobic bacilli and other oursaisms have been identified in this fluid. After Zeltz filtration the fluid is still toxic in most instances. Aub has found that these anaerobic organisms are not normally present in the tissues of man. At present there is no evidence that there toxins are important in the pathogenesis of burn shock in man.

This discussion of burn toxins in relation to burn shock is far from complete and mentions only a few of the important studies that have been made. There seems to be no doubt that many chemicals are released from the area of a burn that all together play a part in the depression of the

circulatory system after a burn. 3 Pain. At the moment of burning and for a few minutes after burns cause sharp pain. Then there follows during the next few hours and, even occasionally for several days, a period of almost complete freedom from pala. At later stages burns may be among the most painful of all ducases. Until recently pain has been considered to be a very important cause of shock following burns. Many experiments have been carried out to evaluate the importance of pain as a factor in various other forms of shock, but in burn shock the only experiments of this kind are those of Kabat and Hedin. Unfortunately their experments on dogs are inconclusive for several reasons, particularly because their burns did not produce shock but merely produced a moderate rise in the bematocrit. Recently the experimental evidence from studies of afferent stimuli as a factor in the production of traumatic shock has indicated a much smaller influence from such stimuli than the many older studies, such as those of Crile, indicated. From an excellent re cent study of traumatic shock in dogs Phemister and Laestar conclude, in part, as follows "No evidence was obtained from these limb traums a flow of nockeptive stimuli experiments that is an important confrom the injured field tributing factor in the initiation of any circula tory impairment or shock which followed."

Evidence derived from the treatment of patients with burns in shock shows that, even in the exceptional instances with severe pain, sedatives have essentially no therapeutic effect on shock comparable to the effects obtained with suitable intravenous finids such as will be described.

4. Cold and beat. Under war conditions and in connection with civilian airplane arcidents some patients with burns suffer from exposure to cold or heat for long periods of time before and after an accident. In peace time civilian life such complications are only seen in disasters of the first magnitude or in the case of individuals living under isolated conditions. Either excessive cold or excessive heat will contribute to the seventy of shock, but quantitative studies of the role played by cold and heat have not been made. Some very important observations on the treat ment of burn shock in a chilled or heated en vironment will be considered in the section on the treatment of shock.

#### B The diagnosis of burn shock

Many writers have described the clinical pic ture of burn shock. As with other forms of shock it is very simple to make the diagnosis in its final stages. One merely has to determine that the pulse and blood pressure are unobtainable. However the earlier periods of impending or mild shock are more difficult to diagnose. Since shock once it is well established is much more difficult to treat than when it is in its earlier stages, it is important to foresee impending shock so that prophylactic measures can be taken.

Careful estimation of the area and of the approximate depth of a burn is important for the anticipation of shock. As already mentioned any patient with a burn area of 15 per cent or greater will probably suffer from shock and any patient with a burn area of 25 per cent will probably suffer from fatal shock unless prompt and active

treatment is given

The pulse and blood pressure should be taken at one-half hour intervals during the first 24 hours. However they are not good indicators of impending shock, since because of the increased penpheral resistance the pulse may remain slow and the blood pressure normal when the blood volume has already been reduced to a critically low level. Suddenly the blood pressure will fall to a dangerous level and even then the pulse may not need.

Direct blood volume determinations are the heat indications of reduced blood volume but they are not practical for clinical work. Hematological determinations are practical and serve accessful guides. Hematocrit hemoglobin and red blood cell determinations are useful Except for research purposes serial determinations at 2 to 3 hour intervals of any one of these is sufficient. The blood examined must be venous rather than capillary blood because of stagnation in the capillaries.

is indicated in Table II apparently normal bematological findings may be seen in the pres-

ence of severe loss of plasma in a previously anemic patient. Note in Table II that a slightly clevated hemoglobin of 110 per cent, if found in a patient whose preburn hemoglobin was 70 per cent, indicates that he has already lost 33 per cent of his plasma volume and 37 per cent of his blood volume a loss that would probably cause severe shock.

Serial plasma protein determinations also provide useful information. As plasma is lost from the vascular bed there is a shift of low protein extravascular (chiefly interstitial) fluid into the blood stream. This results in dilution of the plasma protein. If the shift is rapid there is a greater fall in the plasma protein concentration than in the hemoglobin concentration. In some instances the hemoglobin may remain normal and a falling plasma protein may be the chief laboratory indication of inmending shock.

Acturate records of urine output must be kept Lauson et al. have shorn that renal blood flow and urine output may be markedly reduced at a time when the peripheral pulse and blood pressure are normal. If the urine output its good one may feel sure that the general circulation is good if however the output falls one must anticipate early failure of the general circulation.

#### C Secondary effects of burn shock

The effects of severe burns without shock and of severe shock without burns are similar in many instances. For instance, increases in the blood sugar lactic acid, nonprotein nitrogen, amino acids, ammonia, and hydrogen ion concentration and decreases in sodium chloride and ascorbic acid are common to both. When shock occurs in burns it results in an intensification of the same changes that had already commenced before the shock had started. Quantitatively the severity of these metabolic changes parallels the severity and duration of the shock. One metabolic change, however has been recently observed in shock of various types, including burn shock, that is never seen in burns, no matter how severe, if shock is prevented by efficient treatment. Tayron and his associates (174) have demonstrated the occur rence of fibrinolysis in both burn and hemor rhagic shock. Fibrinolysis is the spontaneous dissolution in vitro of the clots in blood within 24 hours. This phenomenon disappears promptly with recovery from shock.

Another complication of burn (and other forms of) shock is 'irreversible shock. As a result of the anoxia and cellular injury that results from prolonged circulatory insufficiency a point is reached where complete restoration of the blood volume will no longer result in the return of a sufficiently adequate circulation to maintain life. If the systolic blood pressure remains below 50 mm. for more than 3 or 4 hours the shock is al most surely irreversible, and frequently it may become so in a shorter period of time. Studies have not been made on "Irreversible burn shock, but studies (66) on "irreversible hemotrhagic shock have indicated that failure of liver function is one of the earliest and most important changes that lead to "irreversibility There has been discussion in the past of the role of generalized capillary leakage as a factor in the initiation of Irreversible shock. Some observers have claimed that it was important, and others that it did not occur Fine and Seligman (67) have demonstrated why both sets of observers may have been correct in their observations under the limitations of their particular experiments. They have shown that there is no capillary leakage at a distance from the burn or other trauma, or at any place, when hemorrhagic shock is studied, from the commencement of shock or during the whole time that the blood pressure is very low How ever if the shock period has been long enough. generalised capillary leakage starts as soon as the blood pressure is brought up by restoration of the blood volume This leakage under these condi-

tions may be one of the major factors in determining 'irreversibility' Because of the great diager of 'irreversibility' it is imperative to prevent shock when possible and to treat it promptly and vigorously when it occurs.

#### D The presention and treatment of burn shock.

The first principle of treatment of any form of block is to avoid, in so far as possible, any treat ment of the petient that will increase the shock, and to postpone necessary shocking procedures (such as dressings) until shock has been prevented or treated. The positive measures for the treatment of shock are taken up first. Of these measures, those that restore and maintain the blood volume are of paramount importance and are discussed first. Omission of them can into way be compensated for by any of the adjuvant methods of treatment discussed later.

x Human plasma and serum. In burns, as indicated previously, the fluid that is lost from the vascular bed is similar in composition to blood plasma. Consequently, it is logical to replace the set fluid with plasma, and it has been demon strated that burn shock may be prevented or successfully treated in nearly all cases if searchy by plasma transfussions in adequate amounts.

The amount and rate of plasma administrator depends on many factors. First, it should be borne in mind that the amount of fluid lost is roughly proportional to the area of surface burn. However berns of certain areas, such as the face and genitalia, which are highly vascular and have loose subcutaneous tissue are accompanied by particularly high fluid losses. Second, the rate of fluid loss is maximal in the first few bours after a burn and then gradually decreases so that at the end of from 36 to 48 hours an equilibrium is trached between the amount of fluid lost and the amount returned to the blood stream from the interstitial spaces. Third, both clinical and laboratory data must be considered in determin-

ing the amount of plasma to be given.

Progressive hemocronomutation, falling plasma
protein concentration falling blood pressure, and
a rising pulse are indications of impending shock.
There are many formulas suggested for estimating the plasma dosage based on blood concentration (20, 58). The most formorely used is that of
Harkins (89) (a) give 100 cubic continueters of
plasma for every point that the hematocrit or
credit the normal of 45 per cent, or (b) give 30
cubic centimeters of plasma for every point that
the hematolichin exceeds the normal of 100 per oral.

As pointed out previously, such calculations, based on an assumed normal hematocrit may be

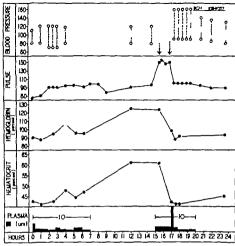

Chart 2. Effect of plasma on burn shock. Blood pressure was not obtainable. (The vertical arrows mean that the blood pressure is not obtainable.)

erroneous if the patient is anemic prior to injury Serial hematocrits should suggest this possibility and calculations should be based on an approximate prebum hematocrit. In addition, such calculations do not indicate the amount of plasma that will be needed to manage the enture course of the burn shock. Consequently frequent hema tological observations must be made during the first 24 to 48 hours. This is well illustrated in Chart 2.

The patient whose course is outlined in Chart 2 was a man of 50 with flame burns of 55 per cent of his body surface, chiefly deep. His blood pressure of his body surface, chiefly deep. His blood pressure normal on entry. Ten units (2 500 c. c.) of plasma were given in the first 7 hours during which time his burns were treated with famile acid and silver ultrate. His hemoglobin pulse and blood pressure remained normal, and plasms infusion was stopped. Five hours later his hematocut and hemoglobin were markedly elevated but his pulse and blood pressure were still normal. During the next 2 hours the patient became chilly nauescated and complained of freeling sick. Sud

denly he became cold, pale and clammy. His pulse was very rapid and threndy and his blood pressure was unobtainable. The administration of 1 roo cubic centimeters of plasma during the next oo minutes restored the hemateorit to normal, but had no effect on the pulse and blood pressure. In the next ro minutes 800 cubic centimeters of plasma were given into the femoral vein by the multiple syringe technique with a return of the pulse and blood pressure to normal.

This Illustrates the necessity of administering plasma rapidly when shock is present. Advantage of rapid infusion in shock is also implied in the recent publication of Kohlstaedt and Page who advised intra-atterial rather than intravenous administration of fluid. However one may construe the efficiency of their intra-atterial administration of plasma to a more rapid administration Caution must be used of course, in infants old people, and those with heart disease. In the nor mal adult with a large burn as much as 2,000 cubic centimeters may be given in a period of an hour without danger of overloading the circulation.

The dosage of plasma on the basis of the extent and location of the burn is also of value, particularly where laboratory facilities are not available. About 100 cubic centimeters of plasms for each per cent of body surface burned should be administered to patients with 10 per cent or more area burn. All of this plasma should not be given according to the following schedule which approximates the rate of fluid loss one-half should be given in the first 4 to 6 hours, one-quarter in the next 6 hours, and the last quarter in the next 12 hours. Smaller amounts may be required in the next 24 hours in zere instances.

Attention should be paid to the clinical appearance of the patient. One of the best guides of adequate therapy of shock is a good urmary out put. If a clinical impression of additional plasma need is at variance with the laboratory findings, the latter should be disregarded. The first 6 hours following a severe burn are critical ones so far as plasma administration is concerned. It is during these first few hours that the physician has the greatest opportunity to prevent shock. No unnecessary delays should be tolerated. When the usual peripheral vems are not available, there should be no hesitation about employing the temoral route or in cutting down on a vein. The use of the femoral route was a lifesaving measure in the treatment of many patients at the Boston City Hospital where at least a thousand of such punctures have been made for withdrawing blood or injecting various solutions intravenously

Another factor influencing the amount of plasma required is débridement. It is common experience that large amounts of fiuld are lost from the body during such procedures as désridement and the cleaning of large burns. The burned kin, although badly damaged and partially permeable to plasma, nevertheless acts as an important dam to the extravasation of flund because of the coagulation of erudates and partial drying of them on the surface. The removal of this barner and consequent opening of tissue spaces is accompanied by an increased fluid loss.

This may be seen by examination of Chart 3. The pattern whose course is described in Chart 3 was a 32 year old woman with fiame burns of 65 per cent of her body surface, chiefly deep who was treated initially with 7 units (1750 c.c.) of plasma given over a period of 12/5 bours. At this time she went into shock despite the absence of significant hemoconcentration. It was known that her bemosplobin pure to injury was about 85 per cent. After a further period of 2 bours, during which time abe continued to be in shock,

infusion of plasma was recommenced and the patent responded with a rise of blood presure to normal. While the infusion was still being administered, debridement was begun. During the course of the operative procedure both the benatocrit and hemoglobin rose abruptly which indicated a considerable increase in the rate of finit loss. Wilson et al. who used cleaning and dibridement routinely prior to tanning, commented on such fluid loss and pointed out the high incidence of shock following this procedure.

Serum may be used in place of plasms with equally good results, as has been demonstrated by its use in large series of cases in Canada and Grat Britain. The reactions which were reported in the early days of serum have not been seen in the later series of cases. Most of the early reaction may have been due to the fact that fresh serum contains thrombin and other substances which are toxic. After a few hours, and certainly after the a weeks during which the serum is now held below me, such substances have dissumered.

before use, such substances have disappeared. a Human albumin. As a result of the work of Cohn and his associates, the United States Navy and the American Red Cross have produced large amounts of human albumin for the treatment of shock. Very little has been available for civilism use to date. A few reports indicate that it has value in the treatment of burn shock (101) At present it is shipped in highly concentrated form (25%) and can, if indicated, be administered without dilution. For emergency treatment of the patient who is not dehydrated it may well prove to have some definite advantages over plasma. It has the advantage that it has a much greater osmotic effect on the circulation than the same amount of protein in the form of pleams. However it has the disadvantage of being a "pure solution that is, it does not contain substances such as prothrombin which are also lost or depleted in shock (174) Zamecnik (198) has shown that in dogs with hemorrhagic shock which are treated with albumin there is a marked fall in the prothrombin concentration, whereas no such fall occurs if whole blood or plasma are used. Janeway and associates have reported a marked full in the plasma globulin in a burn patient who received large quantities of albumin intravenous Additional saline solution and water must be given to patients receiving albumin to replace the interstitial fluid which is drawn into the vascular system by the osmotic action of the albumin.

3 Electrolyte. Saline solution has long been used in the treatment of shock. There is evidence that if it is given intravenously at rapid or moder ate rates of injection the blood pressure of the

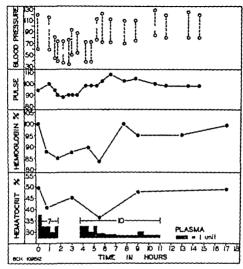

Chart 3 Effect of débridement on rate of fluid loss in a patient with an extensive burn.

shocked individual may be raised but the effect is frequently transient. In addition it appears that plasma protein may be 'washed out" by the saline solution (21) For these reasons saline solution was replaced by plasma or serum in most clinics when these solutions became available, as they dld quite generally in the United States, Great Britain, and Canada between 1940 and 1942 Interest in the use of saline solution alone or in conjunction with other sodium salts has recently again been aroused by the reports of Rosenthal and of Fox. Rosenthal experimenting on mice with standardized burns, has shown that the effects of sodium salts given intraperitoneally or by mouth very soon after the burn are slightly but signifi cantly superior to the effects of serum given intravenously in preventing death of the animals within 48 hours. In his series the effect of the serum appeared to be due not to the contained protein, but to the sodium. He also showed that the therapeutic effect of the sodium sait was due to the sodium radical rather than the acid radical since different sodium salts acted in the same manner Potassium salts increased the mortality Saline solution when given intravenously was not as effective as when given by mouth Isotonic saline solution was more effective than the hypertonic solution Prinzmetal et al have also reported good results in mice with sodium ther any Fox treated a number of severely burned nationts by the oral administration of sodium lactate or sodium bicarbonate and saline solution He gave from 10 to 15 per cent of the body weight of isotonic sodium salts in the first 24 hours. Any vomiting such as occurs frequently in patients with severe burns, was treated by the administra tion of more oral fluid. The results appeared to be good. It must be stressed that in the studies re ported the sodium was used chiefly for prophy laxis and not for treatment of fully developed shock. In addition dangerously low plasma protein levels were seen in some of the petients

This work needs careful consideration. For the moment it would appear that while it is true that there is a deficit of sodium in the burned that there is a deficit of sodium in the burned other substances and, although it undoubtedly is necessary to replace the other substances. It appears to us that sodium salts are necessary adjuncts to us that sodium salts are necessary adjuncts to the treatment of burned back, not the sole there better a possible of the sole there. The work of Moyer et al and Abbott et al on the use of sodium chloride and sodium bicarbonate solutions with whole blood which will be described in the section on whole blood, are of interest in this record.

4. Whole blood Whole blood was used ex tensively to treat burn shock until 1940. Then plasma and serum became generally available in large quantities and almost entirely replaced it. Among other reasons it was widely believed that additional red blood cells could serve no useful purpose when the blood was already concentrated However during the last a years, interest in whole blood has revived, principally because of the work of Moyer at al They studied the therapeutic ef fects of various solutions on the shock of severe, deep burns of dogs. The dogs were shaved and two-thirds of their surface areas were scalded for 30 seconds by water at 85° C. A combination of transfusions of defibrinated blood and gavage of normal saline solution with added sodium bi carbonate solution was the only form of treatment that prevented shock without inducing such complications as cerebral and pulmonary edema in compatible with life The unsuccessful forms of treatment were (1) intravenous administration of saline and bicarbonate solutions, (2) intra venous administration of saline and bicarbonate solutions and dog's serum (3) intravenous ad ministration of dogs scrum with salme and bicarbonate solution by gavage and (4) intra venous administration of defibrinated blood with water given orally ad libitum. Abbott and his associates have found that whole blood transfusions given during the first day of the burn not only aid in preventing shock in human beings, but also alleviate or prevent the subsequent anemia that frequently appears about the third day after plasma has been used. Levenson et al (115) and Evans and Bigger have also treated burn shock successfully with whole blood in a small series of carefully studied patients

5 Glucose The early increased blood sugar in severe burns might be considered to contraundicate the administration of glucose intravenously. However Taylor and associates (176) have demonstrated that there is no impairment of

glucose tolerance or loss of excessive amounts of glucose in the urine under these condition. In addition burns cause depletion of the much glycogen and possibly of the liver glycogen so that efforts should be made to restore glycogen to these tissues by an adequate administration of carbohydrate. Finally as mentioned previously there is an early increase in the nitrogen catabolism and gincose in large amount may alleviate this Glucose should be given in substantial quantities. Harkins et al (or) recommended up to soo grams in the first 24 hours for severe burns. However glucose must be considered to play only a minor role among the many substances given to these patients, and to be almost or entirely without value if it is given in pure solution for either prevention or treatment of shock. 6 Gelatin.

6 Gelatin. Degraded solutions of gelatin have been studied as plasma substitutes in the therapy of burn shock in dogs (147) and the consensus of opinion is that properly prepared gelatin solutions are as effective in the acrot gelatin solutions are as effective in the acrot gelatin solutions are as effective in the acrot class and mortality as plasms. Koop (168) has close to the same conclusion in working with human patients. However plasms possesses a number of properties beyond the osmotic characteristic stated by gelatin and since there are other losses from the blood beyond the loss of comotic properties it would appear that plasms would offer some advantages

7. Gum acacia solution. Although interest in this solution was shown by several investigators up to 1940 in use has completely stopped with the advent of human plasma and serum. And only have these substances been found to be better ter but, sits ocacia has been found to be harmful when given in repeated does (83)

8 Oxygen. The defenses of the body against access of the body against shock and the efforts to maintain blood volume are all in reality attempts to achieve one goal, the maintenance of normal cellular metabolism which is dependent upon adequate oxygenation of the stance. As indicated previously tasue anoris results from the failure of the pempleral circular from the failure of the pempleral circular from the failure of the pempleral circular from the companying shock. Oxygen has been widely used clinically in the treatment of burn shock, but the only clear indication for it is complication of the burn shock by respiratory tract infury.

9 Position. The inducations for raising the foot of the bed or placing the patient in the Trendelenburg position are not as clear in the treatment of shock from thermal burns as in the

restment of simple syncope, since in the burned rationt there is no pooling of blood comparable to that in simple syncope. In the burned patient the find is lost externally or into the subcutaneous tissue, and it cannot be readily returned to the vascular tree by change in position However it appears that the circulation to the brain is improved by tilting the bed even though the blood volume may not be materially altered. It is especially important to raise the foot of the bed during the first few minutes after the onset of shock while other more effective methods of treat ment are being started.

10. External temperature. Because many pa tients in shock are cold it has been customary to cover them with many blankets and also to use bot water bottles or other sources of heat. Blalock has shown that overheating is detrimental to the animal in traumatic shock, and Elman and associ ates (61) have shown that both heating and cooling are harmful to burned animals. As already men tioned, occasional patients have markedly high levers from 18 to 24 hours after a burn. It is important that for patients in shock with a rectal temperature below \$4.0 decrees C. or above 40.0 degrees C. very active measures be taken to warm or cool them promptly but these measures must be stopped as the temperature approaches nor

11 Sedation in shock. As recently as 1942 it was customary to treat burns with very large doses of opinies. Beecher has shown that this is not a safe procedure when shock is present. He points out that morphine is contraindicated in the treatment of fear or hysteria or of any condition in the presence of anoxia. It should be given only to relieve pain. Most importantly he calls attention to the fact that no drug is readily absorbed from the tussies if administered subcutaneously or intramuscularly to a patient in shock. He presents the history of a patient in burn shock who was given repeated doses of morphine subcutaneously without effect. As soon as her circulation was effectively restored by treatment with plasma the whole amount of the drug was taken rapidly into the blood stream and gave the usual effects of an overdose of morphine. Energetic measures were needed to combat these effects. Therefore when opiates are indicated in patients with shock they must be given intra Venously

Another aspect of this problem has been studied by Elman (61) who showed that the mortality of burned dogs was increased when usual doses of morphine or of barbiturates were given. In view of these findings, morphine and other sedatives should be used cautiously in patients with incipient or actual burn shock. Anesthetics have the same harmful effects, and are very dangerous in incipient or actual burn shock. Cyclopropane is safest if one is necessary (21) but Levenson and his associates have found no occasion to use anesthesis at the time of the first dressing in their most recent 500 cases seen during the last 2 years.

12 Pressor drugs. Frank and his associates have recently studied the therapeutic effects of various pressor drugs in irreversible hemor rhagic shock in door. They found no indication of beneficial results from the use of pitressin with or without ergotamine, paredrine commine, or tuamine. Earlier work by Cannon (30) indicated that the capillary blood flow may be actually lowered when such drugs are used. No such studies have been made on burn shock, but by analogy these studies indicate that these drugs would be of no value.

13 Adrenocortical extract. As described in the section on pathology there is evidence of adrenal injury following burns. In addition there is laboratory evidence of increased outputs of adrenalin (150) and of various corticosterolds (24. Rhoads, Wolff and Lee (157) reported promising results from the use of adrenocortical extract in the treatment of burn shock. A more recent report by the same authors reverses this The later clinical observations opinion (158) were corroborated by the experimental studies of Resenthal, who found that in standardized burns in mice there is no protective action produced by either desoxycorticosterone or adrenocortical extract miected subcutaneously when compared with controls injected with saline solution. Lowdon at all had previously reported failure to decrease the mortality of burned animals by the use of desoxycorticosterone. Cope and Moore (45) have demonstrated in dogs that adrenocortical extract has no influence on the abnormal permeability of the capillanes in the burned area. In view of the failures encountered, there is no indication at present for its use in the early post burn period.

14. Vitamins. Govier working on hemorrhagic shock in dogs, has indicated that B complex vitamins, particularly thiamin have a definite therapeutic effect on the shock. In addition to their findings mentioned previously on the effect of burns on vitamins Lund, Johnson Taylor and associates (126) have found great depletion of water soluble vitamins during the shock phase of burns. They believe it is logical to administer large doses of these vitamins early after admission of the patient.

15 Anesthesia and surface treatment. The very serious effects that these items may have on burn shock will be discussed in the subsequent section on surface treatment.

## RESPIRATORY COMPLICATIONS

Injury of the respiratory tract is an important complication of a few thermal burns. It should be suspected in any patient who gives a story of having inhaled large amounts of hot smoke, par ticularly if consciousness has been lost. Patients with injury of the respiratory tract usually have burns of the face, but this condition may be seen in patients with no external burns (68) Singeing of the fibrispae of the pares, soot on the face, and burns of the nasopharynx are commonly seen in these cases. As described in the section on pathology the fundamental lexion is a necrotizing tracheobronchitis. Finland at al found the usual symptoms to be cough, hoarseness, dyspnes, and stridor The sputum was mucoid, purulent, and bloody Occasionally casts of traches and bron chi, resulting from pseudomembrane formation were coughed up. The vital capacity was greatly diminished. Physical examination revealed scat tered areas of dullness, hyper resonance, and rales of all varieties, but chiefly crepitant or fine wheezes. A rays showed scattered small areas of emphysema, atelectasis, and concestion. Sec ondary pneumonia, chiefly due to the staphylococ cus aureus, was seen in some patients.

Any patient in whom injury of the respiratory tract is suspected must be watched very desely A trachestomy kit should be kept at the patient's bedside. Respirations should be charted every half hour Examination of the nose, nasopharynx, epiglottus, lasynx, and vocal cords should be made. If burns of the nasopharynx are present, swabbing the nose with bland oil and having the patient gargle with a warm soothing solution, such as siveose in water will be beloud.

If cough or dyspace develops, the air should be humsliffied. If these symptoms progress in split of humsliffied. If these symptoms progress is split as the progress of humsliffied and poper cent oxygen about lo an oxygen tent. Inhalations of 10 per carbon dioxide and 00 per cent oxygen about lo given for a few munutes every one to two hours to induce deep respirations. The patient should be moved frequently and encouraged to cough. If there is any wheeing or other agras of bronchial spasm, aminophyllin or adrenalin should be given by nebulizer. Generalized lazyugobrocchial spasm may occur very suddenly and may lead to death of the patient unless it is relieved immediately Tracheotomy with artificial respiration may be

necessary Tracheotomy is also indicated if strider air hunger or other signs of larygap obstruction appear. Section through the tracheetomy tube should be done repeatedly as needed. When simple aspiration through the tracheotomy falls, bronchoocopic saviration may succeed.

A dose of 25 000 units of penicillin should be given intramusculity on entry and repeated every 3 hours. If the units output is good, mindiazine may also be given. If the patent is restless, one must first rule out anons, and, if present, steps such as have been described should be taken to provide for oxygenation. For reritesness due to pain, meperidine hydrochlotic should be used rather than morphine or any other respiratory depressant. For restlesness due to nervoussess or anxiety the barbiturates should be used (12).

If the petient with Injury of the respiratory tract has extensive surface burns in addition, plasma should be given without heatstion to prevent or treat shock. Finland found no evidence to indicate that plasma infusions under such curcumstances led to pulmonary edema. Plasma may also very rarely be indicated in the patient with respiratory burns who has no external burns.

## INFECTION IN BURNS

Infection is always a serious complication of extensive deep burns, and frequently or rarely according to the efficacy of treatment, a complication of lesser burns. Its control is, therefore, one of the most important aims of therapy

A. Initial contamination few pathogenic orgaisms since the process of burning sterilizes the skin in the affected area. However unless protected, the lesion is rapidly contaminated. Great sources of serious contamination are the respiratory secretions of individuals handling the patient (33). Also important are the materials which come in contact with the burn and the bacteria that may remain viable in the deep crypts and ducts of the skin in the burned area, of in the skin of adjacent areas.

B Bacteriology In carriul bacteriological studies of burns in patients cared for in a special ward at the Royal Infirmary at Chasgow Clark (33) found that the bemodytic atroptococcus was the predominant infecting organism. This comborated the previous studies of Adriccia in 1933 at the Johns Hopkins and the Boston City Hospitals. However, most of the studies that have been carried on during the last 4 years at many videy separated civilian hospitals in the United States have shown that hemolytic streptococcal infec

tions in burns are infrequent (135 117). They show that burns at all stages are almost always contaminated or infected with several organisms. Aerobic, anerobic, gram positive, and gram nega tive bacteria, and cocci may all be found in any angle culture. The number of varieties of bac terix found is usually related to the care and variety of the culture methods employed. Serial cultures taken from a single burned area show changes from tune to time in the variety and proportions of the different organisms. They also show that the hemolytic staphylococcus is the predominant pathogenic organism. Almost every culture at any stage of the many burns studied by Meleney (135) Lyons, and Levenson (117) have shown it to be present. It has not been eliminated by sulfonamide or penicillin as given to date. Fortunately its mere presence does not prevent successful grafting (117) When the hemolytic streptococcus is predominant, however it does interfere with successful grafting in many cases. Fortunately it may be eliminated by the use of large doses of penicillin (113) or of sulfonamides (3) Acute hemolytic streptococcus infection of the burn with the rash of scarlet fever occurs occasionally in children. It responds well to chemotherapy

Symbiotic infections in which an anaerobic or microacrophilic streptococcus is associated with one or more other organisms occur narely (135) Under these conditions there may be burrowing of the infection at the edge of the wound and destruction of otherwise vuble dermal tissue.

An unexpected finding of Meleney s study was the frequency with which anneroble organisms were observed. However there was essentially no clinical infection with the bacillus welchil or other clostridla except the bacillus tetanl. It must not be forgotten that chincal tetanus is occasionally seen in burns and that tetanus antitoms should be given prophylactically to all patients with deep burns.

The more frequently encountered bacteria are lasted in Table III in approximate order of their importance

The skin in dermal burns retains most of the resistance that normal skin has sgainst infection If rest and avordance of recontamination are provided, any organisms growing on the surface soon die out as healing progresses (42). With deep burns the problem of infection is much more serious because deep burns are always infected from a few hours after the burn until healing is complete. During the first 2 to 6 weeks necrotte alough is present on the surface and it furnishes an excellent medium for bacterial growth. After the slough

TABLE III-VARIETIES OF BACTERIA FOUND COMMONLY IN CULTURES FROM BURNS

has separated the open granulating wound con tinues to harbor bacteria as long as the wound is open. The question of control of infection by local and general measures will be considered later.

## HYPERPYREXIA IN BURNS

Patients with burns frequently have a period of high fever (over 41 degrees C) in the first few days after the burn. This is observed in adults only if they are burned extensively but in chil dren, and particularly infants, it may occur as a complication of small area burns. The occurrence of delinum stupor convulsions, or coma should auggest the possibility of hyperpyrexia. The oral temperature may frequently be musleadingly low. and rectal temperatures should be taken of all such patients. Infants in particular should have hourly rectal temperatures taken during the first 24 hours, and 2 hourly temperatures during the next 24 hours. The pathogenesis of this early high fever is not known. It does not appear to be due to infection since in most instances there are no signs of spreading infection, either at the time of the fever or later Pyrogens in intravenous fluids are responsible only occasionally and dehydration may play a role, but in many cases high fever is seen in the absence of these fac tors. Increased heat production due to the in crease in metabolism as a result of extensive burns together with, and more important, the decreased ability of the patient to lose heat because of the greatly restricted area of exposed normal skin may be important. Walker and Shenken believe that in many cases the fever is cerebral in origin.

The burn patient cannot tolerate a high fever so that if the rectal temperature remains above 41 degrees C for more than a very few hours death is almost certain. I rompt and energetic treat ment directed toward cooling the patient is effective in many instances and this treatment should be started whenever the rectal temperature is above 40 degrees C. If the fluids given have

been madequate, more fined will help but the main attention should be directed to fee water sponge baths to all exposed skin. If less than 50 per cent of the skin is exposed it may be necessary to remove some of the dressings. Windows should be opened, drafts created, bed clothes removed, and an ice water bath made in the pa tient's bed. He should be sponged for 35 hour or more until the rectal temperature is brought to 30 degrees C but not below this.

# PRIMARY LOCAL TREATMENT

# A Introduction.

During the decade from 1930 to 1939, tannis acid, tannic acid and silver nitrate, gentian violet, and triple dye 'displaced to a large extent all former methods of primary surface treatment of turns in the United States and Great Britain and its Dominions. From 1931 to date other forms of treatment have been advocated strongly and have now replaced the tanning methods as completely as the tanning methods replaced the older methods after whether the surface of the colder methods after years earlier.

All methods of treatment of burns have always been based on an attempt to correct some one or more deleterious effects of the burn. Tanne acid was introduced to reduce the external fluid own and to fix postulated toxins in the skin. The dyes were introduced to accomplish the same results and to furnish also an antiespite action. In 1937 Allen and Koch introduced the now well known pressure dressars. They claimed that the pressure reduced both internal and external fluid loss and that infection was reduced by careful initial cleaning and by the rest and protection furnished by the bulky dressing. Originally no antiseptic except bore acid entirent was used.

With the introduction of the sulforamides into the treatment of burns. Pickrell used a solution containing sulfanilamide that was sprayed on to form a transparent eschar. Others used various sulforamide ointments, or merely dusted on the drug and covered it with perroduction or a bland outstend. Gurd combined the cleaning and presume method of Allen and Koch with a sulfathia zole "cream." Others used preformed films containing aufonamides (b) Whether or not sulfonamides were used on the surface they were also given by mouth or parenterally New anti-bacterial agents, such as propamidine, were discovered and used. Finally, with the discovery.

and production of penkellin, it was used loadand parenterally. In order to secure more one pleto rest and more even pressure, pleaster can were introduced to replace pressure dessings is some cases. Recently the washing of burns was given up by Cope (43) and washing, outmests of all kinds, and routine chemotherapy were given up by Levenson and Lund (117). Complete ccision of small area burns on entry with immediate skin grading has been carried out secretily. Delayed excision and akin grading of more are tensive burns have been used by Cope and More (46). Chemical excision of the burn with early akin graft was successful in serious cases (15).

There is still no general agreement as to pomary local treatment. Recently however certain fundamental conceptions have been widely at cepted and have led to a more nearly unified view of treatment. The first of these is that the care of local areas in a patient with burns of any important size is but part of the total treatment of the patient. The second is that the treatment of the patient should be based on methods to correct as far as possible the many physiological and pathologreal changes brought about by the burn. Local pissma loss abould be limited, further contamination prevented, and infection controlled. Any unface application should cause no local or general texis effects. Application of the treatment should be rapid and relatively easy and the least possible attention should be required thereafter It should be stressed, however that no fixed routine can be established for all cases. An understanding of the underlying principles will make it clear when variation in methods should occur

## B Fluid loss

In addition to the harm done by the loss of fluid from the circulation by causing shock, the fluid is harmful to the subcutaneous tissues because it clots there and increases the extracellular pressure with resulting increased fibrous tiesse (75) This results in subsequent impairment of function. This is evident particularly in burns of the hands in which it is often seen that following some dermal or deep dermal burns there is marked limitation of motion of the fingers. On review of these cases it is found that swelling occurs early and persists for some time. In contrast, it is found that in cases of similar seventy in which minimal swelling has been prevented, function is unimpaired (74, 12) It is apparent, therefore, that from the point of view of both local and systemic reactions, one of the features to be desired of any local treatment is that it hmit the amount of internal and external fluid loss.

\*The faramina need nador this name vary. One is Gostons water Brilliant green Arriform 1 Washing of burns. Washing of the burned area opens up previously closed tissue spaces and leads to a considerable increase in fluid loss, as was pointed out in the discussion of Chart 3. The relation of washing to infection will be discussed later.

2 Escharous and pressure dressings and casts. Tannic acid and other escharotics until recently have been widely employed for primary treat ment, in part because of their ability to prevent external exudation of fluid from the burned area. There is no doubt so far as the tannic acid and silver nitrate combination with its rapidly forming eschar is concerned that this end is accomplished. While the use of tannic acid is not desirable because of its toxic action on the liver nevertheless the necessity of prevention of external losses of fluid in occasional dermal burns may be tudged from the following experience experience.

The patient was a 22 month old child weighing approximately 13 kilograms who was admitted to the hospital with hot water scalds involving 25 per cent of his body surface. The burned areas were oozing plasma at a rapid rate. There was very little subcutaneous edema. The surface was treated by the application of petrolatum and pres sure bandages. The external loss of plasma was not arrested and the bandages continued to be scaked with fluid for at least 36 hours. During this time 8 units (2,000 c.c.) of plasma were ad ministered with no hemodilution. This amount of plasma represented approximately three times the plasma volume of the child. In spite of this, shock occurred three times in the first day Had it been possible to prevent the enormous surface loss this very large amount of plasma would not have been required.

It has been our experience that pressure dressings, or casts, applied over outment, have very little effect on the amount of fluid lost externally while the agents which rapidly form eschars do stop surface leakage However treatments aimed at scaling off the burned surface do not and cannot prevent the loss into the subcutaneous tissues. As pointed out by Underhill Harkins (87) and more recently by Glenn and his col leagues (75) this subcutaneous loss in deep der mal and deep burns is considerable and may sur pass the external loss. The latter state that in one of their dogs with burns of the two front feet plasma equivalent to more than one-third of the animal a blood volume passed into the area from the toenalls to the humeroradioulnar joints.

An example of the failure of tannic acid to prevent internal fluid loss may be derived from a re-examination of Chart 2 Shortly after admusion the patient was treated with tannic acid and silver nitrate solutions. Fifteen minutes after such treatment the external extravasation of fluid from the burned areas ceased completely and yet the rising hematocrit and hemoglobin showed that fluid loss continued for many hours. As a matter of fact the presence of increasing subcutaneous edema was easily discernible on physical examination. This subcutaneous loss of fluid has been minimized experimentally in dogs (74) and clinically in human beings, by the use of close fitting plaster casts (12 176) and elastic pressure dressings (5) pressure dressings (5)

# C Local tissue injury caused by surface treatment

It is desirable that no further inlury be imposed on the burned area by the agent used in the local treatment. It has been shown that the escharotics, as opposed to bland outlinents injure viable epithelium. Partial thickness donor sites heal significantly faster under a firm olitiment dressing than under tannic acid and silver nitrate or triple dye (29 97). Healing of dermal burns of the back takes place a few days earlier if olitiment is used rather than either tannic acid and silver nitrate or triple dye (36). Epitheliza tion under a dry gaure pressure (113) or saline pressure (143) dressing proceeds at the same rate as under a petrolatum dressing.

# D Systemic effects of substances applied locally to the burned area

Absorption of certain types of substances from the surface of both second and third degree burns has been demonstrated (132). Therefore, it is important that any agent used in the treatment of the burned area either be not absorbed, or if absorbed, be relatively nontoxic. This is especially important when burns of a large area are being treated. Jaundice and other evidences of liver damage are seen more frequently in patients treated with tannic acid than in those treated with bland ointments (63).

Boric acad ontiment has been used often in the local treatment of burns. Boric acid has no par incular virtues and since it may be absorbed in toxic amounts if applied over a large area of injured skin (150) it had best be avoided and sim ole petrolatum used.

Sulfonamides in soluble form, if used locally may be absorbed in toxic amounts (120). Therefore if used the preparation should remain in effective concentration locally and yet not be absorbed rapidly enough to cause general systemic reactions. Since there is often early oliguria in severely burned individuals, the possibility of

kidney damage secondary to the sulfonamides is increased. A 5 per cent sulfathiancle emulsion from which the absorption is relatively slow has been used with good results (86)

# E. Prevention of infaction

Strict aseptic technique in the handling of burned patients is necessary to prevent additional contamination of the wound.

- I Washing and debridement of burns. Until recently the custom of washing and debriding burns had not been challenged. The characteristic view was that expressed in the following quotation. To cover a burned area with chemical or coagulating solutions without first using every effort to transform it into a clean wound seems to us inexcusable disregard of fundamental surgical principles (5) However it should be borne in mind that a burn is different from the ordinary soft tissue wound initial contamination is alloht and it is rare that subcutaneous tissue and muscle are exposed. The type of debridement practiced in the primary care of soft tissue wounds cannot be carried out in any except very small burns. Even simple washing of a burn has certain disadvantages - the increase in time fluid loss, handling and pain - which make it preferable to omit washing if possible. Routine washing of burns has recently been shown not to be necessary if pressure dressings or casts are used (43, 116) However it is generally agreed by those who do wash burns that it should be done sently and quickly. White soap has been most commonly used rather than tincture of green soap.
- 3 Prevention of further contamination. It is essential that the area be protected from further contamination. When each around a reason are applied, the eachar which is at first intact, soon cracks and further contamination is thereby possible Pressure dressings or casts which remain dry on twisted prevent the entrance of additional organisms. If however the dressing becomes atturated with exudate contamination is possible. This has been minimized by the incorporation of a cellophane membrane in the dressing (14.3).

At each dressing change there is the possibility of further contamination. Consequent, dressings about be done at infrequent intervals. The first dressing should remain in place for about 2 weeks. At the end of this tume most dermal burns are besled and require no further dressing but deep dermai, insized and deep burns are just beginning to slough so that additional dressings are required.

3 Immobilization. The importance of immobilization in the control of infection has been amply

demonstrated The absorption of toxic products, metabolic or bacterial, depends to a large extest, on the lymphatic flow which is reduced considerably by rest of the induced part (12). In contrast to surface sections, pressure dressings with splints or close fitting casts provide for immobilization of the burned area.

4 Chemotherapeutic agents. These agents have been widely used for the control of infection of burns. The sulfonamids have been seed bed locally and systemically but their efficacy is controlling the local infection of the burn has not been clearly demonstrated. When one considers that there is usually a mixture of gram positive and gram negative organisms in the burned am, and, in addition, there is present considerable necrotic tissue and exudate it is not surprising that there is no striking control by the millions mides. In some instances it has been claimed that while the local infection is not controlled, preading infection and blood stream invasion are prevented (13.5).

It must also be remembered that all deep burns will have an open wound harboring organism until the hast grafts have successfully bested and that this may take several months. As it is unlikely that any patient can tolerate effective does of any sulfonamide for this length of time, it is recommended that no general sulfonamide brat ment be given as a prophylactic measure or for any other purpose except for some complication such as neumonia.

Penicillin has been used locally and systemically in many cases of serious burns (117 90, 191 22) When used locally it has the great defect of rapid absorption from the wound. To overcome this objection experiments are being made with special cintment bases such as carbowax! (136) With such a base some penkillin activity may be maintained for as long as 24 hours. A more serious defect is the rapid destruction of penicillin by the action of penicillinares released by bacteria, such as the colon bacillas, that are present in the wound and which are not sensitive to its action. When given intramucularly penicillin has not been shown to reduce in any way the hemolytic staphylococcus infection of a burn Possibly if such an infection were found in pure culture on a burn it might be effective for this purpose, but such pure cultures are seldom seen. Hirshfeld (96) stated that when penicilia was used before and after skin grafting better results were obtained. Levenson and Lund (117) found that it was possible that the change of

\*Carbowax is the sume of sucion of polyhydric glycols. They are water soluble but have the consistency of greene.

technique of dressing in the preparation for graiting associated with the use of pencillilin was more important than the drug. On the other hard, in the few cases in which the cultures from a granulating wound that is ready for grafting in every other way show repeatedly that the hemolytic streptococcus is the only or predominant organism, general pencillin should be used in the dose of \$5,000 units every 2 hours for 48 hours before and after the grait. Under this special condition it has been shown to be very useful

# F Technique of application of a pressure dressing

Under operating room conditions fine meshed gause, dry or impregnated with petrolatum should be applied directly to the wound Over this, sufficient sterile gauze, absorbent cotton, cellucotton, or mechanics waste should be placed so that even compression can be secured by means of a firm, wide bandage. If the padding is fur ambed in large rolls of material from 1 to 2 cents meters thick 20 centimeters wide, and 4 meters long it facilitates the application. It should be emphasized that to be maximally effective the dressing should be applied as soon as permitted by the general condition of the patient, since the greatest amount of swelling occurs in the first few bours following injury. Also since the swelling is not limited to the burned areas, but occurs also in the immediately adjacent areas, these areas must be incorporated in the dressing. In burns of the extremities the dressing must extend distally to cover completely the hand and foot, even if these areas are not burned, otherwise the venous return will be obstructed, and as the back pres sure builds up the arterial blood supply will be impaired. Elevation of the extremity may help to prevent stasis and discomfort. In applying a pressure dressing the tension must be uniform and care must be taken that no more pressure is used than is required. In burns of the chest and abdomen a pressure dressing as such cannot be applied without interfering with the patient a respiration. Therefore, in this location a firm bulky dressing without pressure is used.

# G Technique of application of close fitting casts

The application of close fitting plaster-of Paris casts is recommended for burns of the extremities particularly for burns of the hands, but it is not recommended for burns of the trunk, but tocks or head. Under operating room conditions, one layer of sterile fine meshed gauze, dry is applied to the entire area to be covered by plaster. This is covered with four layers of sterile open mesh gauze, fitted carefully without overlapping.

Plaster slabs are then molded over the extremity front and back. A thin layer of rolled plaster completes a nearly skintight, light, well fitting plaster cast. The cast must be close fitting but must be applied without compression at any point. As in the case of a pressure dressing it should extend proximally from 7 to 16 centimeters beyond the limit of the burn In burns of the ex tremities it must extend distally to cover completely the hand and foot (including the tips of the fingers and toes) even if these areas are not burned otherwise the circulation will be seriously unpaired. Hands should be put up in the position of function with a slight cock up at the wrist and fingers in neutral position. It is all important that directions be followed exactly (12 116) Levenson and Lund have seen instances in which improperly made casts had to be removed to prevent gangrene.

# H The use and technique of petrolatum gause dressings

Allen and Koch Cope (42) and others advise pressure dressings for burns of the face head, and neck, as well as for those of the trunk and ex tremities. After using them on a number of patients Levenson and associates (113) have given them up in treating these particular burns. Two reasons led to this decision. First, such dressings were always uncomfortable when used for serious burns. Second, sufficient pressure could not be used to control the edema of the face or neck They now use sterile petrolatum gauge strips applied without pressure and without bandage. These strips rub off from time to time and new ones are put on by a nurse. They are rectangular and approximately 8 by 16 centimeters. They are made of fine mesh cotton bandage material impregnated with petrolatum and sterilized. Other areas where pressure dressings are impractical are the genitalia and the anus. Petrolatum strips are also used there.

When this treatment is used, the hazard of contamination is increased. However this has and is great in burns of these areas with any known treatment. It may be reduced by isolating the patient, by using sterile bed clothes, and by careful aseptic nursing procedures.

## SECONDARY SURFACE TREATMENTS

The first pressure dressing or cast should be left in place for 2 or 3 weeks except in the few very superficial dermal burns that have probably healed prior to this time. A foul odor contamnation of the dressing by urme or feces, and evidence of infection under the dressing should rarely be

considered indications for a change at any earlier time. If the dressing becomes loose or alips it should be repaired by adding more sterile maternal new outside handages, and new adhesive.

Changes of dressing should be made under aseptic conditions in an operating room. The patient should usually be prepared by a mild seda tive. Anestheria may be needed in rare severe chronic cases at many late dressings. Cyclopropage is the anesthetic agent of choice. On removal of the dressing the status of the wound is appraised and the further needs of the patient are estimated. Dermal burns will usually be healed in 2 weeks but deep dermal, mixed, and deep burns will be covered with soft foul slough Purulent material and loose slough may be wiped off gently but no antiseptic solution should be used. In these cases some remaining slough will be present from 20 to 40 days. The second and all subsequent dressings should also be pressure dressings applied with the same technique de scribed. As soon as large areas have become free of slough and if the granulations and the patient are both in good condition grafts should be applied without waiting for the adjacent slough to separate. In addition to the chemical debridement" which will be described, many varieties of dressings have been suggested to speed the separation of the slough as well as to control infection. In general, every method, and this includes the one recommended here, has disadvantages as well as advantages. Frequent changes of dressings, wet, dry or with ointments, traumatize the wound and increase the danger of bacterial contammation, and the process of changing them is wearing to the patient. Antiseptic solutions or ointments may injure the granulations, the patient, or both and never eradicate infection. Pressure dressings applied to several extremities produce such immobility of the patient that he loses strength rapidly. On the other hand less confining dressings fail to control the pain from friction and allow more contamination. Both are weakening

Tub baths and shower baths have been recommended (137). In general these are difficult to arrange and are infrequently used at present in the United States. A good method of providing continuous or intermittent irrigation with saline or Dakins solution of the extremities has been devised by Bunyan. He uses transparent plastic envelope that has two rubber tubes sealed into its sides. It is troublesome to use.

During the last s years Levenson and associates (113) have abandoned all previous forms of secondary treatment and apply infrequently changed

dry pressure dressings or casts to the extremus and similar nonpressure dressings to the trusk. Even the use of frequently changed wet dressing just prior to grafting has been discarded (11). The only exception to this treatment of these areas is when very small scattered areas of guanlation are left at the edges of the grafts. Under these conditions nonpressure frequently changed petrolatum dressings are used.

## SKIN GRAFTING

Until the advent of the Padgett dermatone he technique of skin grafting burns of large area wa difficult and was mustered by few surgeos. The sumplest technique, but least satisfactory is that of Revertin. Somewhat more difficult, but more astisfactory is that of Thiersch and much medificult, but most satisfactory if successful, are the whole thickness graft and the pedicit grift. There is a great tendency particularly among surgeons who treat burns only occasionally to wait many months before doing any graft to silve nature to make its maximum efforts at being With such a laisses-faire policy burns adjacent to the joints lead to cruppling contractures and deformities.

If Reverdin grafts are used early placed closely and take, they will grow out, cover large area and at least in part, avoid contractures. However the skin surfaces (both recipient and doore) are always aporty' and seddom satisfactory Expertly cut Thierach grafts stretched to somitienson and completely covering a noncontracter granulating surface are much more astisfactory in fact, the grafted skin approaches normal skin appearance and function, and the door site often becomes invisible.

Whole thickness grafts are of very hite moortance in the treatment of large burned area. For small specialized areas, such as the syelling face and neck, they are essential, but the care of such defects is in the field of much more specialized plastic surgery than is within the scope of review. The same is true of pedided grafts.

# Immediate excision and skin grafting

Immediate excision and skin grafting has been carried out by several authors (197). It is theoretically sound because after a deep hum is excised and the wound grafted, the area is healed in a week or 10 days. However it has a very limited applicability and is indicated only in drawnsly deep burns of very small area in which there is little likelihood of shock. Relatively few deep burns come in this category. Even with a small burned area the operation is a long one be-

cause of the difficulty of securing complete hemo-

# B Delayed excision and skin grafting

Delayed excision and skin grafting has been carried out recently in a number of cases by Cone and Moore (46) It is their practice to give large amounts of penicillin intramuscularly and locally through Dakin's tubes incorporated into a pressure dressing at the time of burn From 3 to 7 days later when the shock has been satisfactorily treated and the general condition of the patient is good the burned area is excised and grafted at one operation or grafted later within a few days. If the area is very extensive, the procedure must be done in stages. The same procedure, begun at a later date, between the tenth and fourteenth days, has been followed by Ackman and his associates (3) In their technique no parenteral chemotherapy is given but a sulfathiazole emul sion is used locally. The results of these procedures have been excellent, and the method has great promise in the hands of surgical teams experienced in dermatome grafting operations and in the care of surgical shock. Blood transfusions to the amount of several liters may be needed at the time of and immediately after these operations.

# C Skin grafting after sloughing

Burns are grafted in most clinics in the granu lating stage. The time when the slough is com pletely separated is usually between the third and with weeks. Sloughs on small and more vascular areas, such as the face, separate more quickly than those on larger and less vascular areas. Recently attempts have been made to speed up the time of separation of the alough by the application of various solutions such as the proteolytic en symes, papain (41) or pepsin (100), or by the application of pyruvic acid in a starch paste (39) (chemical debridement) With the latter method the sloughs of deep dermal and deep burns may be removed in from 6 to 10 days without injury to any epithelium that may be present in the more superficial areas, or to the granulation tissue. Some very impressive results of its use in severe burns have been reported

When the condition of the patient is satisfactory the granulations are firm and pink, and the chances of successful skin grafting are good When unsatisfactory the granulations are edema tous and finable, and the chances of successful skin grafting are poor In most cases granulation tissue is not removed. However exuberant but firm granulations, if removed down to a firm yet.

low base, are no contraindication to grafting Bleeding is controlled by warm saline packs or the application of thrombin (51)

# D Technique of dermatome skin grafting

The Padgett dermatome (145) has many ad vantages over the knife or razor for cutting Thiersch grafts. Sheets of even thickness may be cut from parts of the body that could not other wise be used as donor sites. Any thickness of skin, from o 15 mm. to full thickness of the skin, may be taken. Grafts should be between or 5 and o 30 mm. thick. The amount of skin transferable at one operation is limited by the patients general condition. Patients should seldom have more than four drums of skin grafted at one operation. Very sick patients can tolerate only two drums.

I Anesthesia. Although it is possible to cut grafts after infiltration of the skin and subcutaneous tissue with procaine it is much more time consuming and difficult than to cut them under general or spinal anesthesia. Patients with extensive wounds do not tolerate ether nitrous oxide and oxygen spinal or pentothal anesthesias well Cyclopropane is much safer and is very satisfactory Levenson and his associates (113) have used it in several hundred operations with out any complication.

2 Choice of donor sites. Any part of the trunk, the whole circumference of the thigh or arm, and the posterior surface of the calf may be used as donor sites. Smooth areas on the thighs, chest, abdomen and back that are not too hollow or too sharply rounded are the areas most easily used. If the patient cannot easily remain prome for a few days, use of the back will cause post postative discomfort.

3 The operation Before the patient is anesthetized the dermatome knife should be inserted in its slot with the beyel away from the drum and its edge adjusted to cut the desired thickness of skin. This is done by setting the flange plate at zero and bringing the blade flush with the drum by turning the two adjusting screws at the sides. Then, turning the flange plate the required num ber of graduations will set the blade at the correct distance from the drum. The flange plate is graduated so that one division equals 0.025 mills meter. While the patient is being anesthetized the donor site is prepared with any standard method of skin preparation. If the wound dressing is removed at this time care must be taken not to contaminate the donor site, the instru ments, or the team that will take the graft. After sterilization the donor site must be washed carefully with ether to make the akin absolutely dry Then the drum is coated with an even thin laver of the special rubber cement that is furnished with the dermatome. Another layer of cement is then put on the dry skin. This is allowed to dry for from 2 to 5 minutes until it has lost its shiny moist appearance. The dermatome is then emsped in the surgeon s left hand with the back of the blade reating on his wrist. The distal edge of the drum is placed on the distal edge of the donor site and pressed down firmly for a minute. The edge is then raised about 136 centimeters by rolling the drum. The blade is then brought into contact with the skin by the right hand. Cutting is accomplished by short quick strokes of the blade while the left hand rolls the drum slowly toward the proximal edge of the donor site. The skin in contact with the knife should be under slight tension by being lifted by the adherent cement, while the skin about a centureters proximal should be compressed by the drum. After from 1 to 2 centimeters have been cut an assistant should inspect the graft to determine its depth. If it is not correct the cut may be made thicker or thinner by moving the flange. This is done without removing either the drum or the blade from their positions. At times it may be necessary for the assistant to press down on the skin just lateral to the drum to keep this skin from inter fering with the stroke of the knife or from being cut irregularly. When the proximal edge of the drum is reached the graft should be cut free with a separate scalpel. It is then picked up with small hemostata, peeled off the drum and laid on a sponge moistened with salme solution. Powdering the more surface which is sticky from the rubber cement with sulfanilamide will make it much easier to handle. Other grafts are then cut if necessary. After all the grafts to be used are cut. the donor sites are covered with one thickness of fine mesh nylon or rayon and a few layers of gange and towels to protect them from contami-

nation during the remainder of the operation. The area to be grafted is then uncovered, the skin around it aterilized and draped, and the wound surface is cleansed by applying moist sponges which are then removed without rubbing. The grafts are then laid on the wound in the largest possible pieces that fit. When the areas to be grafted are small or irregular in shape the grafts should be cut into pieces that fit. When ever possible, the grafts should come at least to the edges of the wound, and preferably they should overlap the edges algabity. Unless the method of using a "backed" graft, which will be described, is used, the graft should be stretched

to normal aidn tension by satures from 5 to 6 millimeters apart around its edges. A pressur dressing over the graft, which is straped and bandaged into place so that it cannot possibly ally is essential. If the graft is on an extremity a plaster cast fixing the Joints above and below the area grafted is also important.

The donor sites are now bandaged over the tenporary dressing. If the donor site is on the usterior surface of the body arms, or legs, the whole dressing should be removed down to the single layer of nyloo or nyon as soon as the patient is in bed. This should be exposed to the air to allow a dry scab to form which will protect the wound. This should be left in place mill it falls off spontaneously after healing has taken place in z or x weeks.

4. Backing for dermatome grafts (78) The technique just described gives very satisfactory results that is time consuming because in order to stretch the grafts properly it is necessary to use a great many sutures. Usually the suturing is the longest part of the operation. When the grafts must be subdivided it is especially difficult to handle the pieces. Webster has recently shown that pilo limit may be used as a backing for grafts, and Evans (64) has suggested cellophane for the same purpose.

Before a graft with a backing is cut the drum is coated with dermatome cement and the backing film cemented to the drum as smoothly as possible. New coats of cement are then applied to the film and to the donor site and the graft is cut as described. The graft with its backing is removed from the drum and is placed on the recipient site. The backing prevents the normal contraction of the skin that results from its elasticity and gives it added strength. The handling of the cut skin is consequently much easier and any cutting of pieces to fit small or irregular areas is more easily performed. More important, however is the fact that no autures are needed to maintain the graft at its original size and tension. The grait is maintained in place by even elastic pressure provided by a suitable pressure dressing. The back ing is easily peeled off after the graft has healed

Experience with cellophane as a backing material has shown that it is difficult to apply this substance to the dermatome without its which the substance to the dermatome without its which is the control of the contro

PTRe film is the trade none of asserts plants film that is printly plants.

faces that are convex, concave, or irregular wrinkling frequently results. This may lead to aress where serum or blood collects beneath the graft because of poor approximation to the granu ations and over these areas the graft may be lost.

Fine gauge nylon1 or similar rayon has proved to be more useful than cellophane. In the first place it never wrinkles on the dermatome drum Secondly it sterilizes as easily as any textile and does not need special packing in the sterilizer to prevent adherence of its adjacent surfaces. It is unchanged physically after sterilization. In spite of its relative limpness before it is attached to the skin, it prevents contraction of the graft and sutures are unnecessary Grafts backed with nylon conform better to irregular surfaces than do those backed with cellophane. In addition it has been found that it is possible to cut the akin from 0.15 to 0 20 millimeters thick. Such grafts are slightly thinner than those which can be successfully cut and handled without backing donor ates from which such thin grafts have been taken heal very rapidly and can be used again in a relatively short time. On all areas where split thickness grafts are satisfactory grafts of this thickness have given as satisfactory end results as slightly thicker ones.

# E. Homografts

Homografting or the use of skin from some one other than the burned individual is in the nature of a temporary dressing since such grafts disappear in from 3 to 6 weeks. The only permanent homografts have been transplanted from one identical twin to another (23) The blood group as such appears not to have any important bear ing on the success or duration of this type of graft. Homografting has a limited but definite, application in the care of patients, particularly children with extensive burns. With the granu lating areas covered, though only temporarily the general condition of the individual improves so that by the time the grafts dissolve autografts may be made Ackman (2) has had a large series of cases in which these grafts were used successfully

## NUTRITION

As noted in the earlier section on nitrogen metabolism there are great early losses of nitrogen in the urine and losses from the surface of the burn until epithelization is complete. The fact that low plasma protein levels and hypoproteinemic edema occurred late after burns was noted by

This is the 14 worses prion cloth used for purachetes. It is not meet han a sulfameter laket and has servegels of so pounds per sensar inch as safe freedom. The warp! made of so Dender threads, 7 threads to the fact, and the word of so Denser threads, 7 to the fact.

several investigators between 1030 and 1040. A fine report on this subject was that of Clavelin and Hugonot. There was very little of practical value that could be done at that time to improve the nutrition of their patient and an amputation had to be performed. When human plasma and serum became available they were used to combat this nutritional edema and following the attack on Pearl Harbor they had their first large scale clinical trial for this purpose. The results of plasma treatment of patients with edema were in no way as striking as the results of treatment of shock in burns. Plasma is inadequate as a means of combating the edema, which is a nutritional edema, because of the small amount of protein furnished by large amounts of plasma when compared to the needs of the organism. One liter of therapeutic plasma contains only about to grams of protein which as will be indicated is only a small part of the nutritional need of the patient with edema.

The estimation of the status of a burn patient with regard to the presence or degree of protean deficiency is not simple. The factors necessary for a critical evaluation are (1) optimum weight of the patient, (2) observed weight of the patient (3) plasma protean level, (4) plasma albumin level (5) plasma volume, (6) mitrogen intake and (7) nitrogen output. Actually, main reliance in climical work has to be placed on a nutritional history on the patient's weight, and on serum protein determinations done most simply by some densitionneter method.

Elman (60) was the first to stress the patient s weight in evaluating protein depletion. It is practical to weigh bedindden burn patients by weighing them on a stretcher at the time of dressing changes just before the dressing is removed and then weighing the removed dressing and the stretcher. As soon as a surgeon commences to weigh his patients with burns he will be amazed at some of the losses encountered in patients that do not have very severe burns. Losses of more than 25 kilograms have been reported as occurring in a few weeks after a severe burn in spite of efforts to maintain nutrition (128).

Failure to meet the increased nutritional demands of the severely burned patient results in progressive loss of weight and strength edema, friable granulations, increased local infection and, finally, death from maintrition. It is preferable to anticipate the requirements of the patient and to meet them before sever maintrition occurs. In the very severely burned patient this may require as much as five or more times the normal intake of nitrogen. It has been indicated that the principal

foodstuff required is protein. However, the food provided must be an adequate metabolic mixture containing in addition to adequate amounts of protein sufficient calories, carbohydrates, minerals, water and accessory food substances. Whenever possible, protein losses or deficiencies should be corrected by oral feeding. It is not enough for the surgeon to order a 'high protein. high caloric, high vitamin diet. If such a diet is ordered the patient may fail to benefit from the order for any one of the following reasons (1) the diet presented to the patient is not as speci fied (2) the diet presented is not eaten in whole or in part because it lacks palatability there is lack of appetite, and there is a lack of nurses to encourage eating and (3) food eaten may be partly or wholly lost because of diarrhea or vomiting

The three items lasted under No. 5 are interrelated. It is common experience to find that a sick patient has no appetite. However if special attention is paid to the likes and dislikes of the patient and special or other numes are available to encourage eating and to offer means when the patient desires them instead of only at stated routine periods, many such patients will eat a surprisingly large amount of food.

The two items under No. 3 are also related to each other. Forcing the diet in a sick patient does not always result in a net gain. Nausea, vomit ing distention, and diarrhea singly or together are limiting factors. In general the sicker the patient the less fat is tolerated, and the larger the proportion of protein that is required. It has been found that at least 25 per cent of the calories in the diet should come from protein and not over 15 per cent from fat if any of these intestinal symptoms have occurred recently. Some patients will need 50% of their calones in the form of protein. It is well to take a number of days to increase the food mtake, as sudden increases are more likely to be followed by gastrointestinal symptoms. More cautious increases will prevent such symptoms. If the diet is not tolerated, protein in the form of a digest should be tried and frequently will be well tolerated. The available digests are not particularly palatable and should be given by intubation if refused by the patient.

Intubation feeding is important and may be used to increase the intake of food greatly Medium caliber masal stomach tubes are used and left in all the time or for many bours a day. If left in continuously the tube should be removed every third or fourth day for cleaning. About 500 cubic centilineters may be given at a time, spaced between meals and at night but there is a

wide variation in the amount and frequency of supplementary tube feedings that different patients will take. It is well to start with half skimmed milk and half water or with a muture of protein hydrolysate and carbohydrates and in crease the strength and quantity of the mixture over a period of days. Instead of supplying the mixture in intermittent doses, a drup apparation may be used which can, after a short period of training, be regulated by some of the patients themselves. If from 125 to 150 grams of protein and from 2,000 to 2 500 calonies are given by mtubattion in addition to an average bone diet, the patient should receive a total of about 200 grams of protein with over 4,000 calones.

Some of these patients will require protein and carbohydrate supplements given intravenously as well as by intubation. This has already been discussed by Tagnon and associates (173) and by Lund and Levenson (125) and by

Elman (59)

As noted in an earlier section there is an acute hemolytic process starting immediately after an extensive deep burn and continuing for about 72 bours. The actual number of red blood cells bemolyzed during this period is usually relatively small. However following this there is a chromanemia which continues until healing is complete.

This anemia is progressive and its chronicity and severity are roughly proportional to the extent of unhealed deep burn. It does not respond to large intakes of iron liver extract, protein calones, and vitamins, although these must be given for nutritional purposes. Blood transfersors are necessary at frequent intervals and in large amounts to maintain the hemoglobin at a satisfactory level. In the past it has usually been rec ommended that the burn patient should be transfused with type specific blood when the hemoglobin falls below 75 per cent, but it has been learned that he does better when his hemoglobia is kept above 85 per cent. To accomplish this may require as much as I liter or more of blood every week during the patient s entire course of illness. If available, red blood cells suspended in saline solution are as satisfactory as whole blood (172)

The cause or causes of this chronic anemia are poorly understood. One factor may be chronic hemolysus. In support of this concept Moors and Cope (40) have found an increased excretion or ed cell breakdown products. Emerson and Exert recently demonstrated that pooled plasma and type O whole blood given to patients with type A B or AB blood induces a persistent and sever

hemolytic process. This is detected by finding an mcrease in bilirubin in the plasma. Hemoglobinemia and hemoglobinuria are not found Another factor in some cases is loss of blood into the dressings. This is particularly marked when the granulations are 'poor' and edematous in nationts that are not in nutritional balance. The hone marrow is not markedly depressed as the reticulocyte count frequently reaches 5 per cent

# SEX HORMOVES

In severe burns in young women menses cease and do not commence again until healing is nearly complete. At the same time these patients develop an abnormal growth of hair especially on their arms and legs. This hair disappears about the same time menses recommence (115 47) No similar change is noted in men. Attempts to treat the metabolic effects of burns with a growth promoting sex hormone (testosterone) in the early stages have not met with success (24 os) Recently following a suggestion made by Browne (24) testosterone propionate has been used with considerable clinical success in the late stages of burns at the Boston City Hospital. It was not possible to study the nitrogen excretion in these cases, but clinically they responded in a manner that indicated an increased positive nitrogen balance. The pain decreased, the granulations improved, the appetites increased, and weight was gained very rapidly. The dose used was 10 milligrams per day given intramuscularly. This hormone has given this good effect to patients of both sexes.

Pereira R. F. and Tologa, E. E. Dacryosinualita
Simulating a Dacryocanalicultis (Dacrori
nustila simulando una dacriocanalicultis) Sem. and.

The author describes a rather remarkable case in

the author describes a retirer remarkable case in which pus from the ethnold cells was draining when pus from the ethnoid cets was draining through a fistula from the involved anuses and then through a insular from the involved sinuses and then through the superior lacefinal canal into the right

Fluid instilled into the incised inferior lacrimal Find institued into the incoord interior iscrimal which contained a slight amount of pus canal scancil contained a signic minorum of pus passed readily into the nasal cavity apparently asserted the name of the nasal cavity apparently. passed readily into the hasal Cavity apparently through the normal opening into the nose through the normal opening into the nose superior canal was incised but no pus could be excuperior canal was incised but no pus could be excuperior canal was incised. superior cansi was incised but no pus could be expressed from the lacrimal eac. A probe was passed into the nasal cavity in the region of the ethnoid cells and its position verified with x rays

no and the patient was now referred to the ear nose, and the patient was now reteried to the ear nose, and throat department, where the condition was diag. throst upparament, where the common was used to direct examination as hypertrophy of the nosed by direct examination as hypertrophy of the right superior turbinate due to edema of the meatus right superior turbulate due to edema of the meatus on the right side and by roentsenography because on the right and the sinutes on the right side—cs or the opening of an one somewhat the transfer street, the ethnolds and maxillary one a maxillo pecially the eminutes and institute yours a manual ethnoidal sinustra. An operation designated as ethmoids snussus. An operation designated as that of Ermiro de Limas was performed. This operation permits supervision of the maxillary sinus and tion permits our extension on the manually office said at the same time gives access to and permits evacual time of the manual access to and permits evacual at the same time of the manual access to an access to an access to a second access t at the same time gives access to any perints evacuation of the entire etamoid system. At this operation there was encountered intense hyperplasis of the mucosa of the ethmold cells. These cells were full of fetld pus and their intercellular walls were broken

In a few days the patient had healed normally with disappearance both of the secretion into the confunctival sec, and of the fistalous opening into the none. Re-examination a few months later disclosed complete absence of all signs of infection of the none and e-gr fluids passed normally into the none through both the superior and inferior lacrimal canals and the probe could no longer be passed through the firstulous opening into the ethmods region of the none.

De Roetth A.: Hypolunction of the Lecrimal Gland and the Sibgren Byndroms. J Lancet 945, 64 443.

The author states that diminished lacrimal secretion may be due to congenital absence surgical removal, or destruction (by radiation) of the lacrimal gland the presence of toxins, and endocrine dysfunction.

The most marked form of hypofunction is known as filamentary keratikis. The condition is characterized by epithelial filaments which present knobs at their free ends. The less marked type is called kerateconjunctivitus siccs which presents a stringy ropy mucoid discharge, photophobla, burning grit tiness, round gray epithelial dots, and hypothesia of the cornea. The Schirmer test shows only from sto 6 mm, of moistening in a minutes.

Another type of hypofunction occurs as part of the Slogren syndrome in association with dryness of the mouth most, and larynx, due to decreased function of the salivary glands. About 50 per cent of patients with this type of hypofunction bave chronic arthritism.

The mildest form of hypofunction is difficult to recognize It is characterized by rague symptoms such as fatigue or heaviones of the eyes drycens of the nose and month, and difficulty in reading especially by artificial light. However th Schirmer test is positive.

Therapy consists in occlusion of all the puncts, the instillation of tear substitutes such as sodium chloride, egg albumin liquid petrolatum shrodysh or Gifford's solution the administration of ovarian extract, and the removal of foci of infection.

JOSEUA ZUCKERNAK, M.D.

Hymes, G.; Scieral Flap Incision with Scieral Sotures for the Cataract Operation. Arch. Ophia, Chic, 945-34: 374.

The author describes a method of cataract extraction in which a scleral flap incision is made and scleral sutures are used.

After retrobulbar injection anesthesia and akinesia of the orbicularis muscle a superior rectus muscle aiture is inserted for retraction of the cyclail. A conjunctival flap is dissected 3 mm, above the upper limbus, and a concentric wedge shaped seleral flap with its base at the limbus, is then made with the

use of a Lundaguard or Hymes concave knife. This is started at about 1 to y mm, above the upper limbus and the conjunctival stap is left attached to it. The concast section is then made with a kreatone and enlarged with acisson? Before entraction of the extract, a single source is inserted—first through the conjunctive, then through the lower lip of the selers, the upper lip of the selers, and finally through the upper lip of the conjunctive. The loop is laid saide. After the cataract has been entracted the rature is pulled text, and tied

The author is of the opinion that with this procedure, a firmer and more accurate closure of rais ract wounds is obtained and the incidence of post operative complications and of astignation is reduced. JOSEVA EXCENSIAN, M.D.

Chamilin, M: The Effect of Tule in Ocular Surgery Arch Ophila, Chic 1945, 34 269.

The author discusses the effect of tak (generally used on surgical gioves) on the ocular tissues.

In a series of experiments on the eyes of rabbits he simulated the accidental introduction of the line the ocular threes during surgical procedures. He found that tale produces foreign body granulones in most ever

To avoid this undesirable possibility, he recommends directing a stream of saline solution from as irrigator at the surgeon's gloved hands before operation instead of immersing them in saline or other solutions. How the property of the pr

Conley J J: The Treatment of Chronic Suppurative Otitis Media with Penicillin. Arch. Order Chic. 945 4 374

Pendillia therapy is of little help in patients with hironic supportative otitis media which has proved resistant to sulfonantide compounds. The response of chronic supportative otitis media to systemic treatment with sulfidiation followed by ,coopconunits of pendicilin is insignificant. The response of chronic supportative otilis media to local pencifing therapy is good 55 per cent of the cases treated were definitely improved. Granulation tessee and cholesteatoms are not affected by sulfadazine or pendicilin, whether administred generally of locally

The best treatment for acute and chronic supportative otitis media is to provent their occurrence by the prophylactic use of one or both of the chemical and biological therapeutic agents.

NOAR D FARRICART, M D

Moreira, D : Gradenigo e Syndrome (Sindrome de Gradenigo) Fol. med Rio., 945 86, 46.

The anthor reports on a patient with a syndrout consisting of acute cities media, neuralize of the trigeminal nerve, and paralysis of the sixth pair of cranial nerves which was first described by Gradenigo of the Royal Academy of Turin in 1924 and since then known under his name. This is the tenth case

prorted in the Brazilian literature and possibly the

openicum in constant with contralateral paralysis nt from brasi with contrainers a parsiyan.
The patient was a Brazilian mulatto 30 years of ine patient was a praximan mulatto 30 years of age who had stropnic minute and upon admittance had been suffering with a supportating left ear for about so days. After repeated myringotomy and about so days. about so days Alter repented myringotomy and intense treatment with 4 and later 3 gm. per day of milianilamide the condution improved, but some or summamure one condition improved, but somewhat over a month later intense temporal and retro-bulbar headaches occurred and paralysis of the abcolour nesources occurred and paralysis of the su-ducers nerve developed all on the right side. At no users nerve ueveniped an on the right side. At 10 me of the other contigenography show any time did otogopy or roentgenography show and the other continues to show the same of the other continues to show th ture an occasiony or roentigenography snow any endence of changes in the right ear or other (mustoid evacues or changes in the right ear or other (mastold of periods) regions. Lesses, M F and Gargill, S. L.: Thioursell as a Common of Nontronenia and Accommissions of Nontronenia and Accommissions. Cause of Neutropenia and Agranulocytosia. N

The authors treated 62 patients with thiouracil.
Of these, 61 had thyrotoxicosis and I had angins

pectoria. Five patients developed neutropenia and granulopenia. Of these 1 (with thyrotoxicoth) died of agranulocytic angina another of the 3 patients developed a sore throat but recovered 1 patient, with granulopenia, recovered with continued admin intration of thiogracii.

Fifty four cases reported in the literature, and 5 personal cases of neutropenia following the administration of thiouracil, are classified in 5 groups, as fallows:

Group 1 includes 30 cases of asymptomatic neutropenia and granulopenia (often confused with the mild neutropenia and lymphocytosis of toric golter) group 3 includes 11 cases of significant neutropenia, frequently associated with symptoms, especially fever and pharyngits, which readily subsided on discontinuance of the drug the patients sometimes recovering with continuation of the drug group 3 includes 8 cases of severe granulopenia, many with a typical picture of agranulocytic angina, and 4 of which ended fatality

The authors discuss the relative benefits and dangers of thiouracil therapy as compared with the dangers of thiouracil therapy as compared with the dangers of thyrotoricosts and thyroid surgery. They point out that whereas most deaths following thy roldectomy are in patients with severely toxic solitors, thouracil may cause the death of patients

with mild thyrotoxicosis.

In analyzing the possible mechanisms of thiouracil neutropenis, the authors state that marrow biopsies indicate both destruction of mature granulocytes and inhibition of the development of premyelocytes.

Hypersensitivity appears to be the conditioning factor in the production of granulopenia with thoursell. Thioursell definitely falls into the group of drugs that produce allergic manifesta tons—namely drug fever uniterail and other types of with eruptions, and reproductions of toxic symptoms with readministration in small doese. Thyrotoxicosis seemed not to be a factor in agranulocytosis due to thiouracil since it occurs in the absence, and during remissions, of thyrotoxicosis. Dosage and duration of treatment also seemed to be not important.

Both semiltization and desensitization have been observed.

Patients who receive thiouracil must be under constant supervision. Since the coset of neutropenia and agranulocytosis is not detectable without blood counts, it is recommended that white cell counts be made three times weekly. The authors advocate the following treatment of agranulocytic angina smodated with thouracil withorwal of the drug, blood transfusions, and the administration of peniciffin, liver extract, penturolectivele, and yeast.

CLINTON H. THIRNES, M.D.

Lors, J. M.; Stripping of the Vocal Cords. Anii Otsler Chic., 1945, 42-378.

Experimental stripping of the vocal cords in cats established the fact of vocal cord regeneration. Application of this operation to the human larynx confirmed the experimental findings.

All types of benign lesions lend themselves to the stripping operation. Hyperkeratotic papilloms can be cured by this operation.

General anesthesia supplemented by local anethesia induced by the application of a solution of such anesthetic drugs as cocaine hydrochloride or tetracine hydrochloride is the anesthesia of choice. The operative technique has proved satisfactory. The postoperative management with silence or the whispered voice is questioned. Better end results have been obtained by permitting reasonable use of

the voice. Functional results have been good.

The satisfactory results obtained warrant the continued application of the principles of this operation.

Wycia, H.1 Bilateral Intracrantal Section of the Clossopharyngesi Nerret Report of a Case. Arch Near Psychiat Chic. 1945, 54 344.

This brief article gives a concise review of the surgery on the glossopharyngeal nerve and a resumé of the effects of the glossopharyngesi nerve on the

A case report is given of a patient who was oper ated upon with bilateral section of the glossopharyngeal nerve for the pain of carcinoma of the epigest news to the period the nerves a dramatic rise in pharpus. On section of the nerves a dramatic rise in blood pressure, palse and replicatory rate was noted, whereas previous to operation these figures had been at a normal low level, the carotid sinus had not been sensitive to manipulation, and the electrocardiogram was normal. The pulse and respiratory rate remained high for 3 days, and the hypertension per stated for 4 weeks not reaching the preoperative levels until 5 days prior to the death of the patient, when there were signs of circulatory failure. The patient died of suppurative pocumonitis I month after operation due, not to inability to awallow became of the section of the glossopharyngeal nerves ance at all inceposition of the patient suffered no dysphagia, but rather to a constantly aloughing epipharyngcal mass which discharged continuously into the lower pharynx. In and of itself bilateral section of the glossopharyngesi nerve is compatible

Woolf J I : Acute Hypertension with Sodium Pentotial Anesthesis in Neurologic Surgery

Acute arterial hypertension which occurs during the subtemporal approach to the gamerian ganglion has been reported when sodium penthothal ancetheme is used. This rise in blood pressure is well defined and in o consecutive cases averaged

A similar rise in blood pressure did not occur when other anesthesis was used

Further studies were conducted upon patients operated upon for hernlated intervertebral disca under sodium pentothal anesthesia. No elevation of the blood pressure could be demonstrated.

It was also noted that the final blood pressure was higher in both the dislocated intervertebral disc series as well as the gamerian ganglion series when they were operated upon under sodium pentothal anesthesis. It was therefore suggested that post operative shock was less likely to occur under such

It is not possible to give an entirely satisfactory explanation ( the acute hypertension noted ex

clusively in the patients operated upon for section of the sensory root of the gamerian ganglion. It is suggested that there may be a hypersensitivity of the suggested that the control of the superior cerebral vasomotor centers under pentothal anesthesia. Retraction of the temporal lobe may result in widespread pressure or irritative effects although the site of vasomotor atimulation is not known.

No untoward effects were noted as the result of this temporary hypertension during surgery

HOWARD A. BROWN M.D.

# SPINAL CORD AND ITS COVERINGS

Shenkin, H. A., Horn, R. C., Jr., and Grant F C. Lesions of the Spinel Epidural Space Producing Louisms of the option Chautiest opened formation.

And Suff 1945, 511125.

The authors review the spinal extradural compresave lesions encountered in a 10 year period (1931-1944) in the material of the Laboratory of Neurosurgical Pathology of the Hospital of the University of Pennsylvania. These formed a series of 54 cases and comprised roughly 3 per cent of the total and comprised roughly 3 per cent of the total number of mass leasons of the spinal canal. The lesions are classified pathologically and described

Metastatic carcinoma was proved in 9 cases. Of these, 5 patients were over 50 years of age, and 1 (a man with a probable primary kidney tumor) was 37 years of age. Symptoms of root compression appeared first, followed usually after a period of several months, by cord compression. Progression was rapid and the systemic nature of the process was anguated by weight loss. Roentgenograms showed vertebral crosion. In 6 of the 9 cases the primary site of the lesion was never determined. In addition to the kidney tumor primary carcinoma of the lung was discovered in a cases. Decompression gave re lief of pain but falled to relieve the symptoms of cord compression.

All of the tumors were frisble and encircled the dura. The laminac and spines were extensively involved. Five of the lexions were adenocarcinomas, s were aquamous cell epitheliomas, and s were up-

In 7 patients in the fifth to seventh decades of Re myedomas were found. All patients had symptoms of a sudden onset of cord compression. Roentgenograms showed vertebral erosion and complete spinal subarachnold block. In one-half of the cases there were symptoms of premonitory root irritation. Complete studies were made in 4 of the cases and in only I case was the vertebral lesion shown to be an isolated one. There were no alterations in serum proteon and the presence of Bence Jones protein in the urine was not observed in the 3 cases in which these examinations

The epidural mass found at operation was extremely vascular The tumors were composed of closely packed masses of cells resembling plasma cells. As a group, the patients succumbed rapidly the longest survival being 14 months

Six cases of neuroblastoma (sympathicoblastoms) were found. Three of the patients were between 9

SURGERY OF THE NERVOUS SYSTEM

and 13 years of age, and the remaining 5 were 6 and 13 years of age and the remaining 5 were 6 months, 23 years and 67 years of age. The two older patrols had had pain for a period of 6 months prior patrols had had pain for a period of 6 months prior patrols had been partially the diversion of costs in the patients had had pain for a period of 0 months prior to cord compression the duration of pain in the to cord compression the duration of psin in the other 4 patients had been less than 1 month. Roent second of vertebral involvement was second of vertebral involvement was second of the control of vertebral involvement. genological evidence of vertebral involvement was soled in a cased a retropersonneal mass was present noted in a cases a retrojectioneal mass was present in 4 cases and a posterior mediatinal tumor in a and a posterior mediatinal rumor in 5 The tumors appeared blubh red and very case. The tumors appeared blutch red and very rescular and tended to infiltrate into the paraver vascular and tended to innitrate into the peraver tebral number. Walker A. E., and Johnson, H. C.: Principles and Practice of Penicillin Therapy in Diseases of the Nervous System. Ass. Surg 1945, 2 1115

Although systemic penicillin appears in the spinal fluid in only minute quantities when injected into a normal animal or person, the amounts are materially increased and will be sufficient to cause bacteriostasis for the more sensitive organisms when meningeal irritation, caused either by sterile media (such as air in pneumoencephalography) or by bacterial in-

vasion, is present. In intrathecal administration of the drug, the best diffusion and the highest levels are found in intraventricular injection. Injection into the cisterna magna gives the next best results and injection into the lumbar subarachnoid space the poorest. Both of the former routes are too dangerous for any but

very extraordinary cases.

Intrathecal penicillin can produce toxic effects on the nervous system. Twenty thousand units in 1 c.c. of saline injected into an experimental mankey produces transient perianal paresthesias, and in some cases convulsions come, and death. A patient who was given 100,000 units of penicillin in 5 c.c. of saline developed urinary retention, saddle paresthesias, and paraparesis. It required 3 months for these symptoms to clear up Neymann has re

ported 2 cases of convulsions, come, and death when 50 000 units of penicillin were injected into the chterna magna of patients with dementia paralytica. Convulsive manifestations are more likely to follow intraventricular injection of the drug, or its topical application to the cerebral cortex.

In the treatment of specific disease, penicillin should not be used for meningococcus meningitis unless sulfadiazine fails to yield improvement in from 24 to 48 hours. In this disease, intramuscular penicillin (40,000 units every a hours) should be used.

For streptococcal meningitis, intrathecal as well as systemic injection is required. This is also the case for staphylococcal menineitis. In the treatment of pneumococcal menbrits, a

disease that was uniformly fatal before the advent of chemotherapy sulfaduzine plus both systemic and intrathecal penicillin should be used.

In the surgical treatment of compound fractures of the skull, from 5,000 to 20,000 units of either dry or aqueous penicillin may be placed in the wound in addition, systemic penkellin should be given. Before a brain abscess is drained, systemic peni-

cillm (200,000 to 300 000 units) should be given daily At the time of drainage 1,000 to 20,000 units may be instilled into the cavity

Infected meningoceles and meningomyeloceles re

spond well to penicillin therapy
Penicillin has a favorable effect on early neurosyphilis, but tuberculous meningitis, brain tumor, multiple sclerosis, amyotrophic lateral scierosis, and cerebral degeneration are unimproved by the drug ROBERT E. GREEK, M.D.

# SURGERY OF THE THORAX

# CHEST WALL AND BREAST

Govan A. D. T : Two Cases of Mixed Malianant Tumor of the Bresst J Palk. Beck., Lond., 1945,

The following 2 cases of mixed malignant tumor of the breast were reported not only because of the parity of these growths but also because the histological diagnosis appears to be unusually precise and the similarity of the case histories and subsequent development makes them of clinical interest

The patients were admitted to the Queen Elizabeth Hospital, Birmingham England Their ages were 37 nospital, uirmingham England Their ages were 37 and 47 respectively They both complained of a progressive swelling of the breast which developed a discharge from the mpple Examination revealed an enlarged nodular (cyatic) breast which was mobile No other pathological conditions were ellcited

One patient was treated by excision of the breast followed by deep x ray therapy The other was reacted by a mastectomy followed by x ray therapy Both patients made an uneventful postoperative recovery and were discharged to the x ray clinic They were readmitted to the hospital shortly after their discharge, the first patient complaining of a lump in the axilla and the second of a lump in the incison. The patients received further surgical and I ray therapy Death occurred a few months later Secondary metastases to the lungs and spine were

Laboratory examination revealed the growth to be well circumscribed and in parts almost encapfound. sulated It could be divided roughly into cystic and noncy it come be division longing in a pregular noncythe parts which gave the tumor an irregular lobulated appearance. The cyals were irregular and benorthagic They might well have been formed by necrosis of and hemorrhage into parts of the tumor The neoplastic tissue consisted of solid white fleshy masses bearing little resemblance to the usual carci nomatous growths of this region There was no suggestion of irregular or widespread infiltration of the normal tissue such as one finds in carcinoma. At all points the growth was clearly demarcated from

It was at once evident on microscopic examination the normal breast tissue that two types of growth carcinomatous and sarcomatous were present. The carcinoma could be seen to have originated in the main ducts. It was shorn to from the thrue surrounding the hemorrhagic cyst and the tissue surrounding the removable periphery Here and there smaller and more irregular islands of archioma could be seen in the central portun but stemona could be seen in the central potton for the start with the seen in the central potton for the start with the seen in the central potton for the seen in the seen in

It must remain in doubt whether the sarcoms or the second type of growth the carrinoma was the cause of the metastases which west undoubtedly present. There was however, no evidence of lymphatic permeation and the subse-

quent history is one of early local recurrence with later metastases to the lungs and bones via the blood stream These facts would suggest that it was the stream these facts would suggest that it was the sarcoma which had disseminated, and indeed it would seem unlikely that a well differentiated carciwould seem unitary that a went uncerentated carri-noma with relatively few mitoses, would produce blood borne metastases in such a short time.

The sarcoma cells were derived from the muscle the majority of cells were spindles Numerous giant

ceus also were present.
In general the growths were not vascular and little stroma could be demonstrated by ordinary methods but silver impregnation revealed an abun dant reticulum which closely invested the individual cells of the sarcomatous portion.

# TRACHEA, LUNGS, AND PLEURA

Blackburn G., and D Abreu A. L.: Thoracoab-dominal Wounds in War Bril J Sarg 1945 33

The authors analyze 126 cases of thoracoabdomi nel wounds treated at forward operating centers nai would accept a totward operating centers and 74 cases treated in the surgical division of a base and 74 cases treated in the surgical division of a base bospital of the 126 patients treated at forward poperating centers 46 (36.5%) died of the 74 ps operating who reached the base hospital, only 3 died

The distinction between thoracoabdominal wounds and abdominothoracic wounds is important. The and auditinuous and rounds is important. The great majority of wounds belong to the first group the wound of entry is in the chest, and the foreign body or the wound of exit is below the disphragm The thoracoabdominal wounds respond more fa The thoraconnounting would type, and are less vorably than those of the opposite type, and are less vulning that the opposite types and all costs likely to require laparotomy Wounds of the right arde tend especially to belong in this category and ame tenu capaziony a source in the caregory and if the liver is the sole abdominal viscus that is in jured a laparotomy need not and should not be undertaken. Only 8 of 65 right sided wounds had an unuersacii. Omy od vy seus lesson while 30 of 61 left sided wounds had hollow viscus lesions, with a cor respondingly steater mortality among the patients with left-sided wounds. The authors believe that laparotomy should be avoided if possible If how ever a laperotomy is necessary a Kocher's incision ever a inpartition is increased a five in increased will give excellent access. The type of thoracic oper will give excellent access. ation also is subject to variation most British sur geons being content with rib resection and closure group orming the diaphragm of the diaphragm

Nonoperative treatment of thoraconodominal in Juries has a place, especially for wounds on the right name was a place expension to mounts on the right and, but certainty of diagnosis is difficult without radiography A wound may be labelled thoracoabradingraphy A would may be labeled (oursecondwound in the chest, can be demonstrated below the diaphragm (2) hematuria is combined with hemodispursion (2) nematical a communed with near-thorax or hemopheumothorax (3) the presence of a

# picurobiliary fistula is proved by thoracic paracente

Although the mortality rate in those patients who aurive the initial wounding and operative treat ment is low the morbidity rate is high.

The complications in the series of 74 cases were as follows

Hemothorax, 18 cases atelectash, 15 cases subphrenic abscess 12 cases (6 with coincident em pyrma, cemprema ii cases emprema with pleuro-biliary fistula 7 cases lung abscess, 2 cases and

The management of hemotherax is no different from that in a simple thoracle wound Ro-expansion of atelectatic lobes after postural drainage and or acceptant area area produced or annual or annual area breathing exercises is the rule and a course of sulfa diarino is often of value in reducing pyreria where progress is slow Both lung abscesses recorded in the table resolved without operation, but were treated with a course of parenteral penicillin.

The most significant complication is empyeme. All cases of empyems are not due to infection of a hemothorar, aince a considerable number follow lower lobe collapses associated with across effusions that become purulent. It is essential, therefore, to watch for signs of effusion constantly and to perform paracentesis thoracis if clinical or radiological signs develop The diagnosis of picurobilitary fistula is casily made by examination of fluid obtained by aspiration from the pleural cavity Drainage should be instituted early, as loculation is likely if drainage h delayed. Significant diagnostic features of sub phrenic abscess were hertic fever with its constitutional malaire, high leucocytosis local tenderness and swelling, restricted rib movements, a disphragm invisible radiologically with a finid level beneath it and an overlying sympathetic pleural effusion. Disphragmatic hernia is uncommon as a sequel of

The canative missile is rarely seen during opera tion for thoracoabdominal injuries but should be removed if easily accessible. In cases with retained foreign bodies, the liver is a common site, but the fate of retained missiles in the liver is difficult to ascertain. It may be wishful thinking to suggest that they do not often came mischief. A case of fatal abacess occurring in the liver after removal of a

Rotation therapy offers some fresh possibilities in dealing with cancer of the coophagus which has hitherto proved little amenable to curative treat ment. The author's report is based on results obtained with the rotation method of treatment in the past 3 years. The clinical development of carcinoma of the esophagus (the most malignant and most

rapidly lethal form and alto of epithelial cancer) has hitherto been so quickly fatal that it is permissible aiready after a relatively short period of observa tion, to draw certain conclusions with regard to the therapeutic effect.

Experimental studies and measurements on phantoms revealed that the most favorable degree of effect is obtained when the focus akin and the half layer values are as great as possible and when the size of the field and the object, and the density of the latter are as small as possible. With the me of 180 kilovolts o 5 mm. of copper and 15 milliampers. the intensity measured in air is 65 r/min at a ditance of 40 cm., and 42 r/min. at a distance of 50 cm.

Each sitting can thus be given in a reasonably short period of time (10 to 15 minutes) The material was comprised wholly of referred cases. No case was refused, not even at the pre-

liminary examination. A considerable proportion of the patients were severely affected and much midebled a number of them with marked cacheria, and with metastases to the lymph nodes in the neck, to

One hundred and ninety-four patients were treated by tradiation. Of these, 174 (00%) were given rotation therapy Eight patients (4%) were as feeble upon admission that no treatment could be given. Twelve patients (6%) in whom the cancer was situated in the cervical part of the esophages (most of these were women), or at the level of the lagulum (a not uncommon site in men) were siren crossive irradiation to multiple fixed fields but the author believes that the rotatory treatment will aways have the advantage, essentially over cross-fire irradiation through fixed fields by increasing the depth doe rendering the focal does hemogeneous, and eliminating the risk of over-crossing effects.

The screening control requires that the patient shall be scated on a stool which during irradiation rotates about a vertical axis, while the roemigen tabe is fixed in a position with the central ray directed hocizontally Only alight cutaneous reactions were observed, and in spite of large daily and total doses, there were no general reactions except moderate leucopenia nor were there any other unpleasant after symptoms. The total dose, which is reached in the course of from 5 to 6 weeks (sometimes 7 to 8 weeks and a minimum of 3 weeks) is about 5,000 rounteens

The rountgenological diagnosis of tumor in all the cases was verified by microscopy in 113 (60%) Squamocellular carcinomas of the caophagus, which constitute the majority of the carcinomas in that site, are not as highly differentiated as for instance. carcinomas of the tongue and oral cavity and would indicate a correspondingly greater radiosensitivity There is therefore reason to contest the not uncommon belief that nearly all carcinomes of the coople gus are, histologically of a strongly keratiniting aquamoccliniar type, and consequently radioresistant. When the question is of squamocellular carefnomas, which on account of their comparatively slight

480

adosensitivity require a considerable amount of dily radiation, the reaction of the tumor will be all the greater the shorter the full treatment time can the greater the another words the higher single and daily pemane in other words the manner single and daily does can be given. If the treatment is extended ones can be given if the treatment is extended over too long a period there is time for the development of connective these reactions with the result hat not all the cancer cells become destroyed

In 117 cases (four fifths of those fully treated and two-thirds of the total number) complete or pearly complete primary freedom from symptoms was obtained that is almost normal deglutition and roentgenologically marked improvement of the pas numerous market improvement of the deglutition was of shorter or longer duration Recurrences in the cophagm were not infrequent they often occurred above or below the primary stenosis and were then accessible to another palliative irradiation. In many cases the patient was able to swallow right up to the time of death which in most cases was due to metaslases or cacheria. The results so far show an indubi table improvement of the survival curve

Wood, H., and Sweetser H B. Jr : Punctate Cerebral Hemorrhago following Thoracic Trauma U S Nos M Ball., 1946 46 51

On the authors hospital ship a fatalities were excontered from symmetrical diffuse, punctate cerebral hemorrhage secondary to severe thoracite than and multiple fractures. The first case carried to demonstrate of assemblands block concussion the a diagnosis of atmospheric blast concussion the second resulted from a fall. Hastological study of the 2 case revealed hardly any cerebral fat embolism as

a basis for the punctate hemorrhages The first patient, injured by an atmospheric blast had an extensive right thoracic and abdominal conmake, right hemothers, puncture of the right hang one fractured right rib a fracture of the right mmerus and right acetabulum rupture of the splera and liver hematoms of the right adrenal pland, renal bleeding mediastinal hemorrhage, and the benorrhages into the scrous membranes of the theoretic and absoluted modulars.

The second patient was injured by a fall from a thoracic and abdominal cavities beight of 25 feet, which resulted in an extensive

right thoracic contusion fracture of 6 right ribe, right hemothorax and atelectasts (with terminal acute lobular pneumonia) puncture of the right diaphragm and the liver, and hemorrhages into the unaphragm and the aver, and nemorinage into the serous membranes of the pleural and abdominal cavitics. Each case was characterized clinically by progressive come with no localizing neurological

Both patients showed pulmonary fat embolism The first case in which there was fracture of the long bones was much more extensive than the second SLETE A fat embolus was demonstrated in a capillary of the cerebral white matter in the patient cited in case r but it was not associated with hemorrhage No fat embolism was demonstrated in the cerebral

The hypothesis is presented that the force of the white matter of the patient in case 2 traums to the thorax of these potients was transmitted to the venous circulation and resulted in a retrograde wave of elevated venous pressure. The degree of force involved in these cases was sufficient to overcome the barrier of the one set of venous valves located near the termination of each internal jugular vein. From that level to the capillaries of the brain there are two direct, relatively short columns of blood which are unprotected by venous valves.

The most abrupt change in vessel caliber is from the capillaries of the cerebral white matter and the basal nuclei to the great cerebral vein. The venous tract from the capillaries of the cerebral white matter bassl nuclei and upper midbrain to the confluence of the dural sinuses is more direct, and is generally shorter than the tract from the capillanes of the cerebral cortex to the confluence of the sinuses The angles at which the superior cerebral veins enter the superior sagittal sinus and the venus cures the suprant same and the presence of the folds of dura in relation to the ostia of these veins would tend to lend protection to the capillaries of the cortex from a retrograde wave of

In brief a retrograde wave of venous pressure should strike the capillaries and venules of the pressure. cerebral white matter before it strikes those of the cerebral cortex. The force should be less readily dispersed in the white matter than in the cortex. This hypothesis should be subjected to experimental study

The work of Hass on the use of preserved or fascia in the living dog has been extended to patients Especially prepared or fascia appears to heal solidly

Experience with 158 cases, and follow up observa tions on a series of 53 employees of a firm providing routine medical examinations at monthly intervals, are presented There were no recurrences in the lat ter group after periods of observation ranging from to months to 4 years and no recurrences were re ported in the remaining 105 patients.

JOSEPH GASTER, M.D.

# GASTROINTESTINAL TRACT

Somervell T H. Physiological Gastrectomy Bru

The author has been replacing the extensive opera tion of partial grattectomy by the more modest procedure of lighting the atterial supply of the stomach with good immediate results. The opera

tion of vascular ligature has been done in 400 cases, 160 of which have been studied by test mesh before and 3 weeks after operation, and 82 of which have had a late follow-up including the performance o near a new romaway manning me personnence of fractional test meal and a thorough clinical examin tion. In 380 cases of arterial ligature with or wil out gastroenterostomy only I death could be trace ont gastroenterostomy only I death could be trace The minimal operative risk and satisfactory is results of the simpler operation are believed to give

the procedure a claim to superiority In all case i the procedure a cusing to superantry an an cases a which the total acidity of the lasting fake is abon 60, gastroenterestomy combined with ligature of the arterial supply of the stomach is carried out, except in the cases of patients with gastric ulcer as well as a duodenal ulcer or those in whom make nancy is suspected

The operation of trying the arteries in its simplest form, consists of firmly ligating with fine silk about 5 of every 6 of the small branches which run from the gastroepiploic artery to the stomach wall as far up the greater curvature as possible without pulling at the stomach. The sheaf of yessels on the lener curvature is ligated in lots. The arteries at the pylorus and within an inch of it need not be tied The posterior wall of the stomach is then gently pulled through the opening in the mesocolon and it a usually found that further ligations must be done to bring the number of ligated vessels up to approximatchy five-sixths of the total number Gastroje

Junostomy is then performed. When the arteries are tled in this way the usual effect is an immediate and considerable drop in the acidity of the stomach. A hyperacid stomach be comes one which secretes less than the normal amount of acid. Control studies were made by test ing pro- and postoperative acidities in cases of arterial ligature without gastroenterostomy and in cases of gastroenterostomy without arterial ligature. The results of these studies indicate that the reduc tion of acidity is due to the ligation of the arteries

and not to the gastroenterostomy Fractional test meals were done in 82 cases from 6 months to 6 years after operation. It was found that the lowering of acidity peraists for at least 3 years and the late results showed very satisfactory figures both for the acidity of the fasting fuice and for the average total acidlty during the a hours or so after the meal was given. In cases in which the operation of arterial ligature alone was done, without gastroenterostomy, the early and late results were exactly similar to those in which arterial ligature and gastroenterostomy were combined With regard to the incidence of recurrent (gastrojejunal) olcer of the total number of 400 patients in whom this operation has been done, only I has returned to the bospital with a gastrojejumal ulcer This is in contrast to the incidence of y cases of recurrent ulcera tion in a series of 300 cases in which a gastrectomy

had been done during the same period. It is believed that arterial ligation is the operation of choice in all cases of duodenal ulcer with marked hyper actifity Jose L. Lindquist M.D.

Olsson, O : Multiple Cancer of the Colon (Cancer coll multiplex) Ada radiol Stockh. 1945 26 415

The nancity of clinically diagnosed multiple carci nomes of the colon as compared with the figures from the autopsy room suggests of course that many cases of multiple cancer of this region are not being diagnosed. This is of interest to the roentgenologist. who must not rest content with having established the dragnosis of a cancer of the large bowel but should continue his examination to include the entire colon. Even though the referring surgeon be satisfied with the digital or proctoscopic findings of carcinoma of the rectum, in view of the especial frequency of the combination of rectal cancer with a second cancer in another section of the colon (this combination being found in perhaps a half of all the cases of multiple tumors of the large gut), a complete examination of the entire colon should be made since the tumor which is overlooked in these cases may eventuate seriously

The surgeon who refers his patient to the roentgen ologist frequently merely wants the determination of the upper limits of the tumor which he already knows to be present or he wants to know the length of the agmold for the technical operative value of such de termination. He may even oppose the filling of the entire bowel with the shadow producing medium. The roentgenologist, however should not limit his quest for considerations such as these. Of course, the entire colon should not be burdened with the medium when an acute ileus is present, or in the presence of an almost impervious stenois of the bowel lumen. However in the latter case too much importance should not be attached to the fact that the inflowing of the contrast material in retrograde direction is

In making the decision to break off the examination short of the entire length of the colon the prehiminary roentgenogram without contrast substance should be carefully studied particularly in the presence of acute lieus or when there has been a history of attacks of acute or subacute fleus in order to estimate if the succeeding contrast roentgenogram sufficiently explains the history symptoms and present finding. If then for any reason the examination remains a partial one the surgeon should of course be apprised of the fact that the examination is in complete. According to Crawfoord (Aca br. seand 1934, 14) not less than 63 per cent of his 161 patients with an obstruction presented stenoses.

The author appends 5 case histories of multiple cancer of the colon—the rectum and anal sections are included as part of the colon—from a year's material of from 5 to 60 cancers of the colon and from 700 to 800 examinations. In only 1 of these did the reentgenologist fall to uncover the multiplicity of the condition. Jenkina, J. A.: Carcinoma of the Rectum, with Special Reference to Sphincteric Control Autical. N. Zealand J. Surg. 1945, 15, 15

Radical operation for carcinoms of the rectum must continue to be the method of choice in the majority of cases for which surgery is employed. A brief description of the procedure adopted in cases in which the sphincteric mechanism can not be saved is presented. The author prefers a two stage operation.

The first stage involves exploration through a left oblique abdominal incision to determine the extent of the growth and fixity. If conservative preservation of the sphincters is decided upon a transverse defunctioning colestomy is done. If a radical perineabdominal excision of the rectum is not contamidizated a terminal colostomy is performed. The polyuc colon is exteriorized and divided the proximal stump, held by forceps is retained in the upper angle of the wound and the lateral peritoneal passage is closed by suture the distal stump is closed and funsususcepted into itself as far as possible and placed in the pelvis. The abdomen is then closed.

The second stage is carried out about 3 weeks after the first stage. The perineal part of the operation is done first and completed abdominally A vaseline gauze pack is introduced into the pelvic cavity and commencing about the tenth day is gradually re moved. A catheter and tidal drainage prevent the threatening bladder infection.

The author presents case histories and reports his observations with regard to the various conservative surgical procedures attempted, in which the sphine teric mechanism is retained. He cites the literature dealing with various conservative procedures and the indications for their adoption in selected cases Pathologically various reports have modified the earlier hypothesis of the manner of spread of carci-noms of the rectum based on the work of Miles. For example, Pannett states that the rectum can be safely incised 1 5 cm. below the tumor and 2 5 cm. above. Functional results are mentioned by most writers and all appear to be reasonably satisfied with the control achieved. However Kirschner states that even after perfect healing complete continence is rarely achieved because of unavoidable damage to the sphincter and to the nerves of the sacral plexus supplying it.

The author suggests a preliminary defunctioning

The author suggests a preliminary defunctioning transverse colections when conservative procedures are to be followed. A wider sacral exposure with consequent avoidance of splitting the posterior original wall is suggested. The anorectal sphincteric ring is retained intact, as far as musculature is concerned to avoid loss of function. The author believes that after resection of the rectum the patient must depend upon external sphincters for control, and that this control is inadequate when compared to the normal mechanism. No reference could be found in the literature as to the state of the internal sphincter muscle after operation however it is sup-

posed that the intrinsic nerve supply must be abolished. The normal reflex changes which influence the tone of the internal sphincter become inoperative thereby a loss of defectation reflexes occur There is no doubt that the involuntary nonstriped internal sphincter is important in the control of the anal sphincteric mechanism and that it possesses a continuous postural tone that varies slowly in response to reflexes from the bowel above. Al though the condition of the internal sphincter has not been established after resection of the rectum. it has been thought that its tone was dependent upon the integrity of a local nerve plexus and therefore, theoretically it is possible of recovery following intury

Since the external sphincter plays an important part in voluntary and reflex responses to effort and in temporary control its retention with its nerve supply is advisable. Impulses from the pelvic colon may give the patient warning of imminent action of the bowels and this action may be temporarily restrained by voluntary contraction of the sphincter

and externus.

The Hochenegy pull-through operation gives the most satisfactory results in conservative surgery of the rectum in which the sphincteric mechanism is JOHN E. KARABIN, M.D. preserved

# LIVER, GALL BLADDER, PARCERAS. AND SPLEKY

Robertson, H. E., and Ferguson, W. J. The Di-verticula (Luschka's Crypts) of the Gall Bladder Arch. Path., Chic., 045 40 3 2.

The peculiar outpouchings of the mucosa of the gall bladder known as Luschka's crypts, have been so frequently described that there would appear to be nothing important that could be added to the knowledge of their morphology pathogeneau, or complications. However a closer study reveals so many misconceptions concerning them that an at tempt to clarify their anatomic and pathological significance is fully justified.

The gall bladders studied were from two sources 175 from postmortem examinations and 320 from surgical operations. The authors special endeavor was to identify crypts in various normal and pathological gall bladders. Examinations were made of a sufficient portion from each specimen to afford a fairly accurate picture of the relative number and

depth of the crypts that were actually present. Among the 175 gall bladders from postmortem examinations, 112 were judged to be growly and microscopically normal. The term normal" is used to imply the absence of identifiable slens of any pathological condition that could influence the functions of the gall bladder materially or could contribute clinical phenomena of disease. Of the 112 gall bladders, 65 (58 per cent) apparently contained no diverticula. Thirty-eight of the remaining 47 nor mal gall bladders revealed diverticula, grade 1 and only o could be graded a or 3. The conclusion

appears justifiable that anatomically normal gall bladders contain few diverticula and they tend to remain superficially located

The 120 gall bladders that were rem ved by mr gical operation were from patients who presumably had definite signs or symptoms of gall bladder disease. At any rate the proportion of those gall bladders that contained no li erticula was distinctive less than that of normal gall bladders removed at postmortem examination.

The extensive review of the data furnished by the work of others and of the results of the authors investigations gives a perspective which appears to represent a logical solution of the several problems with which the literature has been engaged for the

past 300 years or more.

The following conclusions were drawn

In approximately half of all gall bladders re moved from persons of more than to years of age the mucosa has invaginated the underlying structures, sometimes as far as the peritoncal lining.

- 2 This invagination tends to form deverticular spaces with branching pouches which occasionally almulate mucous glands. They are lined with cothelium corresponding in every respect to that which lines the mucosa of the inner surface of the gall hladder These cells secrete mucus or a mucushke fluid.
- 3 The greater number of the diverticula open into the gall bladder lumen by ducts, which are often tortuous and narrow Some are cut off in whole or ta part from the lumen and become cysts with budifie branches. When such a group is more or less localized, a formation, often called an adenoma, is produced. This is most frequently found in the fundes of the gall bladder but may occasionally involve more, or even all of the sail bladder wall. The term adenoma

is misleading and inantly applied. Multicystic or multilocular cystic diverticula are more fitting designations.

4. The crypta thus formed may contain bile, hile pixments cholesterol crystals or at times, typical biliary calculi. Exudative inflammation may occur in them up to the stage of abscess formation and even of rupture into the peritoneal cavity The residuam of such inflammation may be obliteration of the epithelial lining proliferation of connective there and collections of lymphocytes and other cells.

5 Increased intracystic pressure, absence of a muscularis mucosae a loosely irregularly arranged muscular layer and the independent response of the muscle bundles to physiological stimuli account for the initial diverticulalike indentations. The increased pressure is, more logically the result of neurogenic dysfunctional states of the extrahepatic biliary system although other mechanical factors such as stones and inflammatory obstructions may play etiological roles

6 Except for the complexity of the branches, these crypts correspond in every other respect to the so-called false diverticula of the colon and armaty bladder they are "diverticula of the gall bladder

7 There is little justification except custom, for calling them Luschka s crypts or Rokitansky Aschoff shuses Not only did these investigators not possess sufficient priority but they falled in several important details to recognize the true significance of the structures that they described

Mascheroni H A., Reussi, C. and Boucau E. F: Internal Biliary Fistulas (Las fistulas biliares internas) Prensa med argent 1945 38 2397

Internal biliary fistules may communicate with a pregnant uterus ovarian cysts the pericardium, urelin, or the pleural cavity. However in the majority of cases the fivitial communicates with the duodenum stomach colon or small intestine. According to one set of statistics of internal biliary fixtules were found among 30 000 autopoise. Puestow encountered internal fixtules in 12 per cent of his rabehts with coloevature.

The man cause of internal fistula is cholelithussis or a cancer of the gall bladder less frequent causes are abscess of the gall bladder and echinococcus crits. As to the pathogenesis pressure by a calculus causes an ulceration of the mucosa, which leads to pervisceritis and the formation of adhesions, necrost, and, ultimately a fistula. Penduodenitis as a sequel of duodenal ulcer may also lead to the establishment of a communication between the gall bladder and duodenum either directly or through a fistula resulting from an abscess between both or gans. A cancer of the gall bladder may invade the adjacent tissues and form fistulas leading to the colon in a great number of cases.

No pathognomonic signs are characteristic of an acute internal biliary fistula. Puestow states that suspicion of an internal fistula is justified in patients with a hepatic colic accompanied by chills fever and jundice especially if such as imptoms are frequent persistent, or progressive

In chronic forms dyspepsia may be the only symptom with nausea vomiting and pains following errors in the diet.

Roentgenological studies are of great diagnostic value. The opaque medium may be introduced through a duodenal tube. X ray pictures abould be taken in various positions such as the supine proper pile lateral and Trendelenburg. The presence of gas in the bibary ducts he a rarity but, if detected it points to the existence of an internal fiatula of the bile tract.

Involvement of the liver is a grave complication found most frequently in fistulas leading to the colon Inasmuch as the prognosis of an internal billiary status is always grave surgical intervention should not be delayed although the operative mortality is relatively high reaching 19 per cent. Especially in statitely high reaching 19 per cent. Especially in statit of miss and delay makes the prognosis poor The fact that bille may be aspirated through a duodenal tube is of no diagnostic value and does not suggest toy special time for the surgical intervention.

Persistent jaundice and the presence of white bile in the duodenal contents indicates hepatitis. The author reports 3 cases of internal biliary fistula.

JOSEPH K. NARAT M.D.

Itols, O A.: Tumors of the Pancreas (Tumores de pancress) Arch Sec argest and, 1944, 6 451

The author offers the following classification of tumors of the pancreas

A. Primary tumors (1) benigm unilocular or multilocular cyst cystadenoma, solid tumor insular adenoma, angiomatous tumor and ampullary tumor (2) malignant epithelioma of the head of the pancreas epithelioma of the body or the tail of the pancreas, cystadenoma, carcinoma, malignant in sular tumor malignant ampullary tumor and sar coma of the pancreas.

B Metastatic tumors with primary neoplasm located in the stomach, spleen left kidney small intestine, or lymph glands.

Adenoma and malignant insular tumor produce identical symptoms

Cystadenoms and cystadenocarcinoms have the same macroscopic aspect and only the histological examination will lead to the correct diagnosis. The differentiation of ampullary tumors of the pancreas and neoplasms originating in the lower portion of the common duct offers great difficulties.

If hydatidiform cysts, pseudocysts and dermoids are excluded pancreatic cysts may be divided into two groups congenital and retention cysts.

Cancer of the pancreas forms from r to s per cent of all cancers found at autopuss. Metastases appear in relatively early stages and are found in three groups of lymph glands subpylone, mesentene, and splenic. A fourth group of minor importance is found behind the pancreatic glands

From the histological point of view a types of cancer of the pancreas may be distinguished papil lary cystic carcinoma, adenocarcinoma, the medul lary type, and epithelioma formed by independent cells disseminated throughout the abundant stroma. The last two mentioned forms probably derive from acmi.

Sarcoma of the pancress is extremely rare JOHLPH K. NARAT M.D

Radice, J. C., and Rivero E.: Statistical Studies of 53 Cases of Turnors of the Pancress (Estudio estadistico sobre cincuenta y tres casos de tumores de pancres) Arck. See argent anal., 1944, 6 489

Of 53 tumors of the pancreas observed by the authors 49 were primary and 4, secondary formations 39 were found in men and 15 in women. Two-thirds of the tumors were found in patients between 50 and 60 years of age. The great majority of the patients were laborers. The largest number of tumors were located in the head of the pamereas, to be followed by that of neoplasms in the tail and the body. Married people predominated in the material observed by the authors.

In numerous instances the diagnostic difficulties were great and cancer of the liver tuberculosis blood cysts of the pancreas tumors of the mesocolon

and cancer of the biliary tract were considered. Among clinical symptoms pain occupied the main place laundice colics of the benetic type, a sensa tion of fullness, nausea, biliary vomiting, melena, and hematements were less frequently observed.

Among complications the following were recorded obstruction of the biliary ducts ascites, liver chrhoals fat necrosis brown atrophy of the myocardium

and pneumonia.

The most frequent type of tumors was cancer The malignant degeneration was accompanied by a histological changes fibrosis, acidophil pecrosis, and flattening of the acini. The authors confirm the observation made by other writers that glandular acini undergo rapid destruction by the cancerous tissue while the Langerhams islets abow attempts at regeneration. In a cases an association of the cancer of the pancreas with diabetes was observed. In 1 case the cancer was located in the head of the pancreas in the second in the tail in the third both in the body and the tall and in the fourth the entire organ was invaded

The most frequent location of metastases was the liver, to be followed in descending order of frequency by the lungs lymph glands and peritoneum largest tumor was the size of a newborn child's head

Metastatic tumors were found nearly exclusively in the male sex mostly in the sixth decade of life. with the location of the primary tumors in the gall bladder bileary ducts esophagus, and lungs.

JOSEPH K. NARAT M.D.

Ceballos, A., Brachetto, Brian D., and Rosenblatt, Insular Adenoma of the Pancreas. The First Case in Argentina. (Adenoma insular de pancreat. Primer caso Argentino) Arch. See ergent ARKE GILL 6 100

A woman, age 37 had been complaining for 4 years of attacks of nervousness profuse perspiration, and tremor during the preprandial periods which disappeared after the ingestion of food. Hypoglycemia, accompanied by general debility tremor persoira tion, mental confusion, found at the clinical examination could be relieved by the ingestion of carbohy drates or an intravenous injection of glucose solution. The differential diagnosis involved a spontaneous hypoglycemia or paroxysmal manufestation of some other condition. No signs of an involvement of the liver hypophysis thyroid gland suprarenal glands or the central nervous system could be found. There fore, an adenoma of the Langerhans islets was nunected.

An exploratory laparotomy revealed an adenoma tous nodule situated at the function of the head and the body of the pancress. The tumor had an ovoid shape 13 by 6 mm. in diameter it weighed 1 55 gm and was encapsulated. The parenchyma of the tumor had a whitish color and an adenomatous aspect. The tumor was divided by fibrous bands into alveoli. The microscopic examination disclosed two types of cells ( ) high cylindrical cells with a clear cytoplasm and irregular ovoid uclei, and ( )

low cuboid or ovramidal cells with a chromoolal protoplesm and pyknotic nuclei. The latter type of cells was in the minority TORREST E. NARAT M.D.

Blanchi, A. E.: Pancreatic Insular Carcinoma (Neeldloblastoms) with Generalized Metastams (Carcinoms insular pancreatico [nesidioblestoms] con metastasis generalizadas) Arch Sec. errent. enel., 044, 6 407

Since the publication of the first case of insular adenocarcinoma in 1927 mmerous articles have de scribed benign as well as malignant tumors origina ting in Langerhans blets. In 1018 Laidway suggested the term nesidioblastoma" for tumors originating in the falets and the term neskiloblastoes for hyperplastic reactive changes of a non-neoplastic nature

The author of this article collected from the lit erature 120 cases of benign tumor involving the

cancrestor falets.

He observed such a tumor in a woman, age 39, who was admitted to the hospital with complaints of intensive premenstrual pains in the left acapular region, occasionally radiating to the right aboulder The complaints were of one year's duration. The patient also had pains in the lumbar region radiating into the lower extremities. At the time of admission numerous white or bluish nodules were found seat tered throughout the body. A bloody expectoration

of 3 days duration was present.

Among the important findings the following may be mentioned the blood sugar was 117 albumin. sugar and acetone were found in the urine the Kahn reaction was negative and the blood count and differential count were normal. Examination of the contents aspirated from one of the nodules revealed nondifferentiated neoplastic cells. Aspiration of the liver was done and the microscopic examination showed large cells with round n cici and polygonal protoplasm. These cells resembled those found in the cutaneous nodules. The identification of the neoplastic cells was very difficult. Atypical mitoses were noticed. A blood examination a weeks after admission showed the presence of myclocytes, meta myelocytes, and normoblasts.

The febrile conditi n led to a fatal outcome. The autopsy revealed cystohemorrhagic formations in the liver nephrosis, hemorrhagic ovarian cysts, hemoperitoneum and hydrothorax on the right side. A circumscribed mass was found in the pancress

which showed a diffuse enlargement

The histological examination disclosed a generalized endotheliosis partially solid and partially with the characteristics of a hemorrhagic angioendothe Various staining methods, such as Mallory's and Van Gieson's, and thionine, allowed a diagnosis of a nesidioblastoma originating in the Langerham islets. The author calls attention to the fact that the blood sugar level remained pormal and that numerous metastases spread through the blood as well as the lymph system.

TORDER K. NAMET M.D.

## MISCRLLANGOUS

Etherington-Wilson W Torbion of the Great Omentum. Brit J Surg 1945 33 142

A review of the literature on torsion of the great omentum yields some 190 cases of all varieties, of which 73 can be considered of the primary or ideopathic type. The author reports 4 cases, of which I was primary 2 were bipolar with a pelvic adhesion, and I was swollen and infected by tubercle bacilli. The a pathological specimens are illustrated

The great omentum may twist as a whole or as a part or strand either may be complete (stranguated) or incomplete (congested) either may be primary or secondary Primary twists are necessarily intra-abdominal and unipolar and no definite cause can be ascertained. In cases of secondary rotation, the condition may be unipolar or bipolar, and occur as a result of herma adhesion, omental deformity or past or present intraperitoneal in flammation. The condition may be acute subscute or recurrent. A combination of factors is probably responsible for the causation of omental torsion. such as Perustaltic pushes by the muscle of the intestines abdominal wall, and diaphragm sudden jerky body actions and rotations direct blows omental disfigurement by tumors overloading or uneven fat distribution pedicle formation scarring raggedness adhesions and bipolar attachments duplacement of the omentum during operation or by abdommal tumors. A history of all such causes is found among the cases recorded. A partial twist having started and caused congestion of the veins with edema, it has been suggested that the shorter and firmer arteries may complete the omental Males are more often affected than females, which may be accounted for by trauma or exertion. The condition is uncommon at the ex tremes of age.

The condition is rarely diagnosed or even suspected. Over 80 per cent of cases are diagnosed as appendicitis, and a much smaller number as per located ulcers or cholecystatis The following points are worthy of notice and should lead to the correct diagnosis on occasion The patient probably from 20 to 55 years of age, and a male gives a history of right-sided abdominal pain which gradually gets worse, is often in spasms and is usually relieved by lying down. Other symptoms and signs are not pronounced and are of little differential value Tendemess and rigidity are not impressive. There may be a history of undue exertion or accident, and a hermal scar or sac may be present. The palpation of a doughy tumor in the midline or to the right, often above the appendix is a suggestive sign.

The treatment consists of early exploration The omentum, or a part, is almost always removed. Occasionally as in one of the cases reported here the unstrangulated omentum is simply untwisted Apart from complications which are remote, few patients have succumbed to the abdominal condi-

JOHN L. LINDOUST M.D.

Eaton, R. B : Forward Abdominal Surgery Canad M Am J 1946 54 19.

The author relates his personal experiences and observations, and the lessons learned during the surgical treatment of 230 patients in a Forward Sur gical Unit at an advanced Surgical Center with the R.C.A M.C The experience began in Normandy and ended in Northwest Germany and Holland Twenty-one of the patients had acute abdominal lemons all others presented battle casualties of first or second priority There were 18 deaths.

The time interval from injury to operation the distance and the extent and site of the infuries are stressed as the most important factors in the out come of the cases. In abdominal cases the optimum time was from 6 to 8 hours and the distance from 10 to 15 miles. The optimum time for operation after resuscitation had begun was left to the judgment of the resuscitation officers who became exceedingly skilled in their ability to determine the correct moment for surgical intervention. Pulse volume and the restoration of peripheral circulation were considered the best guides to the optimum time for surgery Blood pressure was considered of less importance as it was often difficult to get the blood pressure above 80 to 90 mm Hg thus a stable blood pressure plateau was of more importance than the height of a single reading. If the optimum time for surgery was missed secondary resuscitation was usually impossible and a state of irreversible shock was likely However, no abdominal case was con sidered hopeless until a laparotomy had been per formed even though the response to resuscitation was not good

The diagnosis was usually obvious and clear cut. It consisted mainly of determining the general condition of the patient, and the number and course of his wounds. Audible peristalsis usually ruled out an intraperitoneal lesson, but flank wounds with lacer ated colons were exceptions. Chest wounds produced transient abdominal signs which were con fusing but which disappeared with rest and resusci tation. Exploratory laparotomy was resorted to when there was doubt as to the existence of intra abdominal wounds.

Routine exploratory laparotomy incisions were used in most cases but occasionally transverse in cisions from the outer border of the erector spinae to the rectus muscle were used. They gave excellent exposure for flank wounds with kidney involvement, and made it possible to deal with the kidney first and then open the peritoneum to explore the peri toneal cavity Abdominal laparotomy wounds were occasionally carried through the costal margin, which was reflected to give good exposure of the disphragm. liver and cardia.

The rule for the management of large bowel wounds was mobilization and exteriorization Mul tiple wounds of the cecum and ascending colon re quired exteriorization, while less extensive ones could be sutured, and in both cases a short-circulting fliotransverse colostomy was done. Occasionally

wounds of the eccum and ascending colon were sim ply natured and a drain lineared to the area. Spura were feasible with left colon colostomies but gave difficulty and if used should not be over a inches long. Multiple wounds of the colon, and pelvicolon wounds were autured distal to a safety colostomy. Drainage was done in all cases of large bowel con tamination.

Small bowel wounds were preferably autured. Resection was necessary for multiple wounds and for wounds involving the meentery A single long resection was preferred to multiple abort ones. End to-end anastomosis was preferred, with a doublelayer running suture and a few interrupted relalayer running suture and a few interrupted rela-

forcing sutures. Wounds of the sphem were always treated by sphemectomy. Wounds of the stomach were closed primarily with care to watch for posterior wounds when an anterior one was found. Wounds not be pancreas carried a high mortality and were treated by suture and drainage.

Lacerations of the liver were handled by deep sutures and occasionally were reinforced by omentum, but packs were avoided Drainage to the site of injury was considered essential. Bladders were closed in two layers with a cystostomy, care being taken to place the suprapuble take high in the fundus of the bladder

Spilled Intestinal contents and blood in the peritoneal cavity were carefully stocked out at the baginning of the operation. Abdominal wounds werclosed in layers interrupted chromic capit (No. 2 or 3) sutures were used except in the peritoseem. Sulfatiation was med in the peritoseem cavity but the walte was questionable. Sulfathiazole-pendiffile bowder was dusted into the wounds before design of

the skin.

The patients were kept from 10 to 12 days, and postoperative care was meticulous with adequate blood plasma, and fluids. Penicillin (100,000 units per 24 hours) was used routinely and sulfs drags were used when indicated.

Complications were few Evisceration occurred in only 2 cases. Peritootiks, as it is known in civilian practice was rare and only 1 patient was thought to have died of general peritonitis (not proven by post mortem examination). There was not a single instance of feed fistula in this series of cases. Other complications were those usually found in extensive abdominal surrey. Farmacy C. Horsan, M.D.

Macdottra, E. and Baldi E M: Acute Torsion of the Fibroid Uterus (Volvulo de utero fibromatoso o torsion aguda de utero fibromatoso) Rev med quir pat fem B Air 1945 13 512.

Two cases of acute torsion of a fibroid uterus seen during 6 years on an active gynecological service are reported. The patients presented themselves with signs and symptoms of an acute gynecological abdomen, having had trouble for 6 months and 2 or more year, respectively. There were severe intermittent shodminal pain fever and tachycardia but no signs of direct peritoneal involvement. A lower abdominal mass was palpable which produced pain on motion. Pelvic examination confirmed the presence of a nodular mass in the pelvis which prevented definite palpation of the uterus. A diagnostic sign of importance is considered to be the detection of the pulse in the uterins artery anteropic.

Both cases were considered to be torsions of the uterms body on the cervir around the long aris of the organ. These torsions were partial as the cervir was parted in the process and incomplete because the rotation was less than 360 degrees. The authors suggest volvulus as the diagnostic term when the cervir is not included and arial rotation when both body and cervir are implicated). This displacement explains the anternorly palpable pulse of the uterine artery.

Both patients were subjected to subtotal hyster ectomy and made uneventful recovery

# ADMEXAL AND PERIUTERINE CONDITIONS

Culiner A. The Relation of the Theca Cells to Disturbances of the Menstrual Cycle J. Obri Gys. Bril Empire 1045 52 545

The author introduces this article with a review of a previous study on the relationship between theca cells surrounding the ovarian follicles and disturbances in the menstrual cycle of the baboom. He believes that in the human being many menstrual species have been attributed to the presence of stretic or cystic follicles, while consideration of the accompanying masses of these cells has been neg

The material from which his conclusions have been drawn for this discussion was collected from ovaries and uter obtained at operation upon women who had complained of excessive uterine bleeding or other symptoms of endocrine disorder. There is no tabulation of the cases but a running discussion is given in which the development and changes in the theca cells are described for the primordial follicle corpus interim arteric follicle lutern cyst, and the corpora ableans.

The author describes luteinfaction of the theca cells around arretic follicles in ovaries with a co-existing corpus luteum, and differentiates between the luteinized theca and granulosa cells by the presence of blood vessels in and about the cells of the theca. Such vessels were not found to permeate the granulosa cells, although in corpora lutes the vessels extended between the lobules of the cells, but not among the cells themselves. He noted an intense vascular response with capillary hemorrhage into the interatices of the theca cells as a frequently associated finding in diffuse theca lutenization.

Theca cell Intelnization around atretic follicles may be without clinical significance in ovulatory cycles. The formation of extensive areas of lutein theca cells may be visible macroscopically around the follicles but in other instances the association with the follicle may not be readily apparent. The most frequent type of change noted was one in which the cells were found to be similar to those seen as the paralutem cells of an approximately 30 day old corpus luteium. Similarity to the cells of the adrenal center was emphasized.

The author states that the character of the uterine reactions associated with these cells is such that neither estrogenic nor progestational influences can be attributed to them. Their activity suggests to him a third overlan homene which may exert androgenic activity or a modified secretion of the known varieties which is capable of distorting the balance between simultaneously acting steriod homenes of the mensitual cycle. Ground Beadanna M.D.

# EXTERNAL GENITALIA

Novak, E. and Stevenson, R. R.; Sweet Gland Tumors of the Vulva, Benign (Hidradenome) and Malignant (Adenocarcinome) Am / Oht., 1945 50 642

The most common location of sweat gland tumor of the vulva is on the labia majora and the next most common is in the paralabial skin or perineum. The gross appearance of the lesion varies. It is always small rarely reaching a size larger than that of a cherry and usually not over 1 cm. in diameter. It may present as a small firm subcutaneous nodule like a small skin fibroma, covered by intact skin. In other cases it is soft, resembling a small sebaceous cyst, for which it is commonly mistaken. Not in frequently there is a small superficial granular area on the surface. If pressure is made on the small nodule, one is apt to be surprised by the fact that. instead of a typical sebaceous exudate the material expressed is reddish brown and pulpy. This should at once suggest the real nature of the lexion. There is no pain and often no tenderness or soreness especially when the skin surface is intact, and the nodule is ordinarily quite movable. In a consider

able number of cases the nationt herself has not noticed the podule, its removal being incidental to

vaginal operative procedures.

The sweat gland tumors of the vulva constitute a relatively rare but highly interesting group Clini cally they present as small and innocent looking growths on or near the vulva, but to one not familiar with their histological appearance the microscopic picture is apt to be rather startling and perhaps lead to the diagnosis of adenocarcinoma. However in only I case in the literature that of Eichenberg was there apparently unquestionable evidence of malig nant change, both clinical and microscopic. All other cases, including the 15 cases reported herewith, were clinically benish and all have been cured by almple excision.

Granted that the characteristic microscopic pic ture of these growths might well in other tissues lead to the diagnosis of adenocarcinoma, there would seem to be no justification for applying the term adenocarcinoma to these notoriously benish sweat gland tumors. It is entirely possible, and perhaps even probable that some instances of the rare primary adenocarcinoma of the vulva may be of sweat gland origin, as in a cases of the group included in this article. Such an origin however is difficult to

establish. Fifteen cases in white women are reported, the

youngest being 28 years and the oldest 67 EDWARD L. CORDICIL, M.D.

## MISCRILANEOUS

Aguilers de Alvarez, M. D : Action of the Synthetic Estrogens on the Metabolism of the Lipids (Accion d los estrogenos sinteticos sobre el metabolimpo d los linidos) Arch farm. bloquim., Tucu main, 945 1 3 3

This study concerns the relationship between the estrogenic hormones and the metabolism of the lipids in the mammal, and compares the results of the author with those obtained by other authors in the vivinarous vertebrates. The syn authors in the viviparous vertebrates. thetic hormones were used exclusively since they are the easiest to obtain and their results are, in general, similar to those of the natural hormones. By the lipks the author means that beterogenous group of substances characterized by their insolubility in water and solubility in the so-called fat solvents such as ether, chloroform boiling alcohol, petroleum and other. The tissues of the experimental animals used (castrated and normal rats) were extracted with alcohol and ether according to a slightly modified method of Bloor Total phospholipids were extracted and determined according to Fiske and Subbarow with the photometer of Pulfrich. The choline frac tion of the phophoslipids was then determined by the technique of Marenzi and Cardini (J Biol., Chem 1943, pp 363 371) also the values for sphingomye lin. Finally the values for cephalin were calculated by subtracting those of the choline phospholipids from the total phospholipids, and the lecithin was

calculated by subtracting the values for sphingomyelin from the choline phospholinids. The author's determinations are given in extensive tables in the original article, and in every instance compared as a norm with the figures given by the aforecited work of Marenzi and Cardin

In all the organs of the noncastrated animals injected with stilbestrol propionate there was a rela tively marked decrease in total phospholipids, with no change in the plasma values. The lecithin showed an increase in the brain and kidney and a decrease in the heart and lung without appreciable change in the spleen and liver the cephalin exhibited an appreciable increase in the heart and blood plasma. but otherwise had decreased more than 90 per cent. In the normal animals injected with propionate of stilbestrol the sphingomyelin displayed an enormous decrease to mere vestiges in some organs or even to complete disappearance.

In the castrated animals the movement of the values m every instance tended to follow those exhibited by the normal animals except that the changes

tended not to be so pronounced When the values for the cited lipid fractions are compared with the values for total phospholipids instead of with the normal values established for noninjected animals by Marenzi and Cardini, it is seen that in normal, that is, noncastrated, animals with injections of stillbestrol, the lecithin shows a

tendency to increase, while in the castrated animals, it has a tendency to decrease, the cephalin following the inverse course. Although the sphingomyelia decreases in the castrated animals, it does so in a lesser degree than in the normal animals. Castration seems to inhibit in part the effects of the stillbestrol

on the phospholipids of the tissues. JOHN W BEREIGHAN, M.D.

Schaub I G and Davis, J E.: The Significance of Streptococci Isolated from the Female Urinary Truct. Bull Johns II phins Uasy 1945, 77 372

A review of previous reports in the literature clearly shows that with the exception of alpha and gamma enterococci (often grouped as streptococcus lecalis) the relation of streptococci to infection of the unnary tract has received little attention. The present authors have determined the incidence of streptococci in a senses of 9,052 consecutive cultures from catheterized urme specimens of obstetric and gypecologic patients.

The organisms were isolated and identified by accepted procedures, and classified as follows. alpha streptococci, beta streptococci, gamma streptococca, alpha and beta enterococci (streptococcus fecalis) and microaerophilic streptococci. The beta streptococci were further classified into serological groups A B C, and D, and "streptococcus-group not determined. This last group included organisms that had falled to react with antisers of the other four groups. It is the group A bets strep-tococci which are highly pathogenic for man, the cause of the acute and severe streptococcus infec

tions, and the most frequently isolated from clinical material

In the authors series streptococci occurred in 7 160 enliness, an incidence of 11.8 per cent of the total number of cultures. Of the total number of streptococci 54 per cent were alpha and gamma enterococci so per cent were alpha streptococci 12 per cent were beta streptococci and the small remainder were divided among the other categories. Organisms of the highly pathogenic group A beta streptococci were found in only 3 cases in the entire series. The relative incidence of these organisms indring by their incidence in other clinical matenal is the reverse of what might be expected Therefore, the case histories of too gynecologic nationts from whom these organisms had been noisted were studied in order to determine the nathorenicity of the various streptococci in the female unnary tract.

Streptococci were found to be the sole cause of clinical disease in 25 2 per cent of the cases reviewed and were found to be involved with other organisms in 28 8 per cent. They were regarded as etiologically

significant in 54 per cent of the cases

The relative occurrence of the various streptococci with escherichia coli was studied and it was determined that the alpha and gamma enterococci were unvolved with escherichia coli in a significantly higher percentage of cases than the other streptoocci with the exception of the gamma streptococci with the exception of the gamma streptococci.

In an per cent of the patients from whose urine streptococci were isolated, no clinical evidence of urinary tract disease could be found in the history. The authors suggest the possibility in these cases that the attreptococci may have been the cause of a past disease or may be responsible for future exacer bations of urinary symptoms.

L. JAMES TALBOT M D

Stoltz, H: Mailgnant Tumors of the Female Genital System (Tumores mailgnos do aparelho genital feminino) An. brasil gin., 1945 20 327

A review of the cases of malignancy of the female generative tract seen over the 10 year period from 1933 to 1945 and an account of the improvement of the facilities for conducting such work at the Clinica Ginecologica de Facuildade Nacional de Medicina of the University of Brasil in Rio de Janeiro are presented. The results are in accord with the general figures with regard to the location of the neoplasm age and race incidence as well as the histopathological types and relation to the births.

On the basis of severity these cases are classified into four groups according to the League of Nations standards. Of the cases of cancer of the cervix (234 cases) 7.3 per cent were early cases and only 32 9 per cent were in groups I and II combined.

The most frequent organ involved was the uterus Among the 277 cases (29 recurrent lesions) including lesions of the bladder sigmoid colon, rectum mesen tery breast, and uterus lesions of the uterus ac counted for 234 of them 220 being in the cervix, 4 in the cervical canal and 10 in the body

The treatment given is determined by the degree of invasion the histological type, and the presence and extent of secondary infection. Surgery radium and roentgen therapy are used in various combinations. Some details of the irradiation technique are myen.

Much improvement in diagnostic and therapeutic methods has occurred. For the first five year period the results may be given as follows of 114 patients treated 16 died during treatment and 31 were given only palliative therapy. Of the remaining 67 10 or 14 9 per cent presented clinical cures after a period of 5 years.

The local socioeconomic factors influencing admission for early diagnosis as well as the end results are dracussed. Numerous detailed tables are presented showing the frequency of location of the lesions by organs percentage distribution by degree of Invasiveness in cervical lesions frequency of the hato-pathological types in all organs, the age color and parity factors concommitant disease incidence the family hatory of neoplass previous surgical operations and the frequency of various therapeutic methods which were applied.

#### OBSTETRICS

#### PREGNANCY AND ITS COMPLICATIONS

Leverton, R. M., and McMillan, T. J. Meat for Pregnant Women. J. Am. M. Ar. 1946, 301 134.

The importance of adequate protein intake to mother and child has been well established. The investigations endeavored to see the results from the simple dictary recommendation "Eat plenty of mest—have a generous servine at least twice a day"

Private patients, all under 33 years of age, were selected. In addition to 3 regular meals per day they received 3 ounces of lean meat. Two control groups were used. All the women were about in the same stage of pregnancy and had the same hemoglobin. One group was given vitainia B complex supplement, while the other group received no supplement. These additions to the diet of meat and Vitamin B were begun early in the fifth month of pregnancy and continued for three mouths siter delivery.

The women whose intake of protein was augmented by receiving a 5 once serving of meat daily had higher hemoglobin and red cell values, less edema, and more success in lactation than the women who received a supplement of B complex or those who received no supolement.

CATHERINE B. HEIR, M.D.

Ware, H. H., Jr., and Winn, W C.: Ectopic Pregnancy South II J 1945, 39 44.

The early diagnosis of ectopic gestation is dependent on the following

1 Abdominal pain usually unflateral, frequently described as harp landnating stabling or testing, but sometimes crampilke and usually intermittent even though dull. The pain usually has a definite onset and is frequently noticed after exertion de fecation, and sometimes after intercourse. The exercity of abock is in proportion to the rapidity of

severity of shock is in proportion to the rapidity of orset and the amount of internal hemorrhage. 2 A careful history which reveals an irregularity of the menses, either in interval or amount and in

duration of the flow Amenorrhea for one month or more is frequent in ectopic gestation.

3 The presence of a unilateral tender boggy pelvic mass, which was diagnosed in 60 patients, or 51 per

cent.

4. Manipulation or pressure on the cervix. This

causes severe pain in most cases.
5 Slight bloody vaginal discharge, which was

observed in 75 per cent of the patients.

6 A rapid pulse rate associated with low hemoglobin, and a normal or alightly elevated temperature. This is very suggestive of ruptured ectopic gestation.

7 Pelvic examination. This should be extremely gentle and limited to one if possible.

Titus says "Expectant treatment for an ectopic pregnancy at any stage and in any location is highly hazardous, as the sac may rupture without a moment's warming and the patient die from the ensuing hemorrhage." The authors emphasize that operation for removal of an ectopic pregnancy should be done as rapidly as possible after the diagnosis is made. Casaus Baron MD

Barnes, J., and Browne F J: Blood Pressure of Rolativas of Patients with Tozemia of Late Pregnancy (Preliminary Note) J Obs. Gys. Brit. Empire, 1945, 52 559.

The authors present a prelimbary report on a study which is in progress to determine what part, if any a familial tendency toward hypertension plays in the eriology of the toomias of pregancy Estimations were made on 240 blood relatives of 192 patients who had been admitted to the obsertire unit of the University College Hospital in London because of tunemia. Estimations on a courte group of 65 relatives of 47 patients who were normal were also made.

There was no demonstrable difference in the blood pressure recordings between the relatives of towesic and those of the control patients except in the group of towesic women with essential hypertensions gradual that proper charge with preparancy. In this group it was perhaps significant that 16 of 18 mothers showed defaults hypertension. Geomes Bakowaya, M.D.

Catro, J. A.: Brow Presentation. Four Cases Observed in the Maternity Clinic in Bookta (A projecte de la presentación crificion en posición de frento y de cratro casos observados en la Cinica de Maternidad de Bogotá). Rer elsi, gís. Caracia, 945, 5. 46.

In 4 instances of labor in brow preentation, ill in young primiparas from 50 to 50 years of age, the purguancy had been completely normal will delivery at term of normal bables of about normal weight from 9 600 to 3740 gm. In silt, the petr's and birth canal was without abnormality yet the duration of labor was markedly beyond the normal for this type of presentation and so infant was delivered sportaincomely. One child however was the only mortality

In the first patient premature rupture of the memnecessary. Attempts at conversion of the present toon into the face or vertex variety, and attempts at high forceps failed, and a dead child was delivered after to bours of labor by a high, laborious tacotripy. After this amount of manipolation the patient's prespection was naturally stormy with fever a painful uterus, feld lochis, and endomentists.

In the second case the membranes were ruptured after nearly a days of labor and the cervix was dilated to a diameter of a cm. However after a fur ther y hours of strong pains the head was still mobile and dilatation had not greatly advanced a cesarean section was done with happy results for both the mother and child

Opposition of the relatives to a cesarean operation and the slow but relatively favorable progress in the third delivery of this series induced an expectant attitude, at least until dilatation should be complete. This decrino was made at consultation 33 hours after the initiation of labor at which the consultants insisted that delivery would occur spontaneously in a few hours. Yet 13 hours later after 5 hours of powerful labor pains and although dilatation was complete and the head had rotated from the mento-posterior to the mentoanterior position the mem branes had not yet ruptured, and the consultants now acknowledged the necessity of interference. A difficult forceps operation resulted in the delivery of a lurng child.

In the fourth mother of this group the fetal head became fixed in the pelvis to hours after the initia tion of labor and an hour later the membranes reptured prematurely with rapid dilatation of the cervir. Eight hours later in the presence of continuous volent labor efforts the head became fixed in the right mentoposterior position a finger breadths from the penneum. A relatively easy forces poperation resulted in the extraction of a living child in the

mentoposterior position.

His own experiences and a perusal of the medical herature brought the author to certain conclusions which he hopes may prove of value to the practicing physican.

These conclusions are rather briefly as follows
I Brow presentation causes grave dystocia even
with a normal pelvis and small fetus

2 Spontaneous delivery in this condition is rarely seen.
3 In the presence of concomitant complications

crearean section is frequently an adequate procedure and the least difficult one.

4 Recourse to sedatives and antispasmotics is of

4 Accourse to sedatives and antispasmotics is of great value while waiting for spontaneous delivery and while preparing for intervention.

5. The technique of procedure should be chosen stronting to the individual case to safeguard the life of the mother and child the operator being guided, of course by the following considerations (a) a restonable period of waiting (b) resort to cesarean section when vaginal delivery can be anticipated to cause difficulty and there is still time for surgery (c) the use of forceps when the head is fixed in the Pelvis with deep anesthesia and previous episotomy (d) symphysotomy if indicated and finally (e) basistoripay when the expectant period has proved a fallure, or when negligence or lack of comprehension of the physician renders this disagreeable procedure obligatory.

6 Patients with brow presentation should be transferred to a specialized clinic or hospital to be cared for by a competent personnel and where creavishing will be ready to cope with any complica-

tion which may arise

7 The obstetrician should be above everything a good doctor and combine common sense with his technical knowledge John W Briman M.D

Thomas, R. C.: Rupture of the Rectus Abdominis Muscle during Pregnancy J Obst.Gyn.Brit.Em fire 1945 52 580

The author reports on his second case of ruptured rectus abdomnis muscle during pregnancy. The number of such cases reported in the literature is 31 Eighteen of the 31 cases gave a history of respiratory trouble 5 occurred with the onset of labor a followed a fall and 1 case occurred after labor during the course of typhold fever Of the 31 patients, 3 were primagravidas 24 multigravidas, and in 4 the parity was unknown. The treatment in 20 cases was operation 4 of the patients died

The difficulty in diagnosis is great, shown by the fact that in only 9 of 32 cases the correct diagnosis

had been made.

The symptoms in the author's case that of a 34 year old para vi who was 33 weeks pregnant, were faintness pain in the right side and vaginal bleed ing with a history of bronchitis for a weeks Exami nation revealed Cullen saign and an extremely tend er uterus most of the tenderness being above the uterus. The hemoglobin was 40 per cent. Surgery was advised and to ounces of fresh and old blood were removed from the whole length of the posterior aspect of the rectus muscle extending up to the right costal margin and down to the aymphysis pubis. All of the bleeding vessels were tied and the cavity was packed Five days after the operation the patient went into labor and delivered a 3 pound 12 ounce stillborn female CATHERINE B HESS, M.D.

Shute, W., and Browne, F. J.: The Prevention of Premature Labor. J. Obst. Gyn. Bril Empire 1945, 52, 570.

A series of 65 cases of threatened premature labor with a resultant salvage of 73 per cent is presented. This problem is acute according to some statistics. In 1941 there were 144,693 fetal and neonatal deaths in the United States. The estimated number of premature births in the United States in 1942 was 155,000 and 33 500 of the premature infants died in the first month of life. The solution of the problem does not seem to be in saving premature infants but rather in preventing premature infants but rather in preventing premature.

In this study it was found that a tendency toward premature labor could usually be predicted by finding a blood estrogen excess in early pregnancy. This occurred in 87 per cent of the 38 cases tested. A blood estrogen test is made routinely at the patient s first prenatal visit. This serves as a guide to the danger abased.

Patients developing uterine tenderness, sacral backache spotting loss of amniote fluid or a feeling of prolapse or impending menstruation are treated with Vitamin E. Only large daily doses of from 75 to 125 mgm of alphatocopherol are effective. These and larger doses can be given throughout pregnancy

until term. This was the only therapy given with or without temporary rest in bed

Among the 109 patients included in this and a previous report, there were 6 monsters and 92 normal living children delivered.

#### LABOR AND ITS COMPLICATIONS

De Gou ea, L. R. L.: Delivery of the Transverse Presentation (O parto em apresentação córmica) Arch brasil med 945 35 39.

This article comprises a rather complete discussion of delivery of the transverse presentation, and includes as references.

A brief historical review indicates that the condition was recognized even by the more primitive races and that they undertook some measures for its correction.

Consideration of the etiology incidence varieties, diagnostic meneuvers, clinical course prognosis, and prophylaxis are presented in considerable detail as

are the methods of treatment. The author's own cases, no in number were seen over a 4 year period. The incidence based on a 37 month period from June 1 1941 to 1949 1 1944, revealed transverse presentations in 64; per cent of 3753 single pregnancies and in 3 per cent of 3753 single pregnancies and managed 3 were single pregnancies. Of the 10 cases managed 3 were single pregnancies is was of wind pregnancy (second child) and 1 was an abortion. The cause for this presentation in 9 of these cases was believed to be due to failure or inability of the uterus to maintain proper control over the fetus either because of laxity or flacedidity of the former or small size of the latter and in 1 case it was due to multiple pregnancy.

Two cases of spontaneous delivery occurred once by conduplicatio corpore with a macrasted 8 month premature niant and again by the mechanism of Douglas in an abortion occurring in the sixth or seventh month of pregnancy. Two cases were managed entirely satisfactorily by version and extraction. Five cases in which the fetus was deal were managed by destinative operations—decapits tion—without maternal injury. One case with ruptured uterus and peritonitis was seen the woman had been in labor more than 48 bours because of a prolapsed hand. Laparotomy was performed but the nation and the more than a second of the processing of the second of the

#### MISCELLANGOUS

Gordon, C. A.: Hemorrhage as the Most Frequent Cause of Maternal Death. An Analysis of the Puerperal Deaths in Brooklyn, 1944. Am J Surg. 945. 70. 77

Each year since 1938 the Brooklyn Committee on Martenai Welfare has analyzed in detail the maternal mortality. In 1944 there were 51 of 52 that and 62 deaths, a rate of 124 per 19,000 this represents a reduction of 8.1 per 19,000 over 1940.

Thirteen deaths occurred early in preguancy to from abortion and 3 from ectopic pregnancy. To renia was responsible for it deaths 6 infants were undelivered. Infection caused the largest number of deaths—50. Ceaarcan section was followed by 8 deaths (6 from infection and 2 from hemorrhaps). Ruptured uterus accounted for 6 death (3 spontaneous, 2 following version and extraction, and 1 after forces delivery).

Hemorrhage was considered as the primary cause of death in only 8 cases and as a secondary cause in 3 more cases however in reviewing the cases the author states that serious bemorrhage occurred in 35 cases. He does not believe, however that it was the primary cause of death in all instances.

Although definite improvement in the material mortality was noted, forther advances are be made. The record of deaths from bemorthage is proof that the precautions against death from tha cause are inadequate. Blood plasma is not sufficient in replacing the lost blood, the importance of adequat amounts of whole blood cannot be overemphasized nor can delay in replacement be condocted.

J ROBERT WILLSON, M D

## GENITOURINARY SURGERY

## ADRENAL, KIDNEY AND URETER

Larsen K.; Method for Examination of the Func tion of Each Kidney Separately scand 1945 123 56

The question of function of the individual kidney is highly important to the internist. The author found that insertion of ureteral catheters for measurement of individual kidney function was too maccurate because urine ran alongside the catheters into the bladder He presents a formula for calcula tion of the function of each side designating the amounts of urine produced by the right and left kidneys in the experimental period respectively as Dand S the amounts of urme collected through the right and left ureteral catheters respectively as d and s and the bladder urine as Bl He gives the following equation D+S=d+s+Bl

If the urea concentration of the urine for the right and left ureteral catheters and from the bladder is respectively Ud Us and UBI the following equa

tion is also true

 $D \times Ud + S \times Us = d \times Ud + S \times Us + Bl \times UBl$ . From these equations D and S and afterward the clearance from each kidney may be calculated easily After introduction of the ureteral catheters the blad der is lavaged and emptied with a catheter after removal of the cystoscope Then precisely 100 ml of water are introduced into the bladder and the collection of unne from the ureteral catheters com mences. At the conclusion of the experimental period the portion of the bladder content which will run freely is evacuated After this the collection of unne from the ureteral catheters is discontinued and immediately 50 ml. of water are injected into the bladder and withdrawn immediately after the first 10 to 15 ml. are discarded the following 10 to 15 ml are collected for analysis If the urea concentration of this portion is designated as USk and the urea concentration of the bladder as Ubl that part of the bladder content that was not evacuated at once can be calculated from the equation

**1**×UЫ=('**1**+50)×USk

Therefore the amount of bladder urine is bladder content minus 100 In the second equation the last term is replaced by bladder content in ml XUbl The results are controlled in the experiments by the determination of both the urea and creatinine clear ance. This method is especially suitable for uni-lateral kidney lesions. Error may result in patients with pronounced hydronephrosis DAVID ROBERBLOOM, M D

Rabort F., and Magaidi, P : Renobronchial Fistula (Fistula renobronquial)

A woman, aged 30 years was admitted with com plaints of persistent cough and pain in the left flank.

Nine years prior to admission she had had a stone removed from the left ureter and for 1 year she had had left scrofibrinous pleurisy accompanied by renal

colic.

One year prior to admission she had noticed a painful tumeraction in the region of the left kidney A physician made an incusion from which malodorous pus escaped The remaining fistula has been treated with curettage local and oral administration of sulfanilamide, injections of prontosil and drainage. Injections of liplodol into the fistula did not clarify the situation Hemorrhagic purulent expectoration and subfebrile temperature did not yield to injec

tions of calcium gluconate The local examination disclosed a fistula in the left costolumbar region from which a dense purulent secretion was escaping. The urine contained a con siderable amount of pus. No tubercle bacilli were found in the sputum The sedimentation rate of the erythrocytes was accelerated \ ray studies of the chest showed a diffuse shadow at the base of the left lung suggestive of a pachypleuritis Poor elimina tion of uroselectan injected intravenously was noticed on the left side Ascending pyelography showed sodium bromide solution in the left lung Prontosil injected into the fistula appeared in the sputum Indigocarmine injected intravenously appeared in the right ureter 5 minutes later while no dye was found in the urine from the left ureter for 15 minutes

A left nephrectomy was performed and the patient after the injection

made an uneventful recovery The authors conclude that a renobronchial fistula, although a rare complication should be kept in mind if a patient with symptoms of a previous renal or perirenal lesion complains of persistent cough with a purulent sputum Nephrectomy usually cures the pulmonary process.

Fontaine, R., Forster E. and Ambard D: tirpation of the Aortiorenal Ganglion in the Treatment of Painful Hydronephrosis (Lextir pation du ganglion aortico-rénal dans le traitement des petites hydronéphroses douloureuses) Res chir Par 1945 64 110

After unliateral nephrectomy the function of the remaining kidney is improved when the aortorenal ganglion is removed. The same favorable result is obtained in cases of painful hydronephroals. The different surgical methods are discussed

Resection of the splanchnic nerve and resection of the superior part of the lumbar sympathetic are mentioned as alternative methods to extirpation of the ganglion In 7 of 9 cases the result was excellent partial improvement was obtained in 1 case and no success in I

Not only does extirpation of the ganglion give definite and lasting relief to the pain and colic, but it improves the function of the kodney at the same time. It is still an open question whether the dilatation of the renal pelvis and ureter is also favorably influ enced by the operation. The treatment is causal rather than symptomatic.

WHENTER M. SOLMER, M.D.

Cristol D S., Mc Donald, J R., and Emmett, J L.; Renal Adenomas in Hypernephromatous Eldneys; a Study of Their incidence, Nature, and Relationship. J Urel Ball., 1946, 55–18.

The resemblance between renal adenoma and car clnoma has been apparent to many pathologists. The material used in this study was derived from surgically removed kidneys which were the sites of proved Grawitz tumors. A total of 567 kidneys and contained tumors were examined. The microscopic sections studied consisted of (1) 122 lesions suspected of being cortical adenomas, and (2) numerous sections of renal carcinomas located in the same kidneys from which proved renal cortical adenomas had been removed. The diagnosis could be verified in only 37 of the suspected renal cortical adenomas. All but one of these adenomas were largely papillary in structure. The exception was one that suggested an alveolar structure. As has been pointed out by many men writing on this subject, too often an adenoma will exhibit characteristics of more than one structural type. The largest adenoma in the series measured 4 mm. in diameter The smallest was barely perceptible with a hand lens. More than r adenoma was found in 7 kidneys. The largest num ber of adenomas in any 1 kidney was 7. As with other investigators this series would indicate that there is an increasing prevalence of adenomas as well as of carcinomas in the decades past middle life.

Adenomas appear in the renal cortex as single or multiple grayad white yellow or brown nodules. They vary in this from that which is hardly discernfile through a hand lens to the size of a walnut. Many are multiple and they are frequently found in both kidneys. Adenoma are seen to occur more frequently in kidneys containing clinical cancer than in significant series of kidneys examined at autopsy Reasons are presented for considering adenomas as

malignant growths.

Ackerman, L. V: Mucinous Adenocarcinoms of

the Pelvis of the Kidney J Urel Balt., 1946, 55 36.

The case of a 66 year old man who presented a mucinous admocrations of the renal pelvis is reported this is the first case recorded in the literature. The patient experienced attacks of renal cole at sanual intervals 1 as years. Eight years previously and at that time a left rephretionly was done. The kilney showed parenchymal destruction so that it was only a few millimeters thick in many zones. The pelvis and unter showed alteration of the linking pithelium with evidence of chronic inflammation. Some areas showed equations metaplasia and this

gradually underwent a transition to zooes of piled up epithelium with vacuolated much containing cells which resembled morphology of the large lowel. In areas there were papillary projections similar to those seen in rectal polyps. The renal corter showed hyakinized glomerull and some cystic formation with flattened entitledial indire.

Six years following the nephrectomy a nonrainful swelling developed in the left flank along with abdominal enlargement which suggested intraperitoneal fluid and nodular masses. Under the left nephrectomy scar there was found an irregular mass firmly attached to the underlying atroctures. The urine showed much albumin with pus, bacteria, and occasional red cells. A needle biopsy of the mass showed a few cells forming actni, along with intra cellular and extracellular mucm. The patient died within 6 months and the autonsy demonstrated a mucinous adenocarcinosus involving the liver diaphragm pleurs stomach, pancreas, and small bowel with lithusis of the right kidney and squa mous metaplasia of the pelvic epithelium. The significance of the spread is that it was not to the regional lymph nodes but resembled that of a pseudomucinous tumor of the overy

The author asks the interesting question as to why the left renal pelvis underwent glandular meta plasta and the right pelvis, squamous metaplassa. ROSSET LEG. [8, M.D.

Fish G W and McLaughlin, W L.: Liposarcoma of Kidney; Report of a Case Presenting an Unusual Syndrome. J Urel Ball., 946, 55 35.

The authors report the case of a 35 year old while femal with liposarcons of the right kidney which is the eleventh such lesion reported and the serenth so reported in an individual with the theorems calcrons syndrome (knobbly hardening of the brain). In addition, a additional cases in children are menoused (z) that of a boy of y years who showed tuberous sclerosis of the brain, and (s) that of a boy of y presenting the classical features of tuberous sclerosis, and although death ensued of cerebral kences an articry was grower.

stons an autopsy was refused.

Tuberous scienosis is discussed briefly in the article and attention is called to the concomitant findings of greasy gray red lealons of the face (adenome sebaceum) in butterfly patterns and mental deficiency coupled with convulsive sciences. The presence of renal pathology is referred to and said to consist of either a single renal lesion although more often multiple bilateral neoplastic areas of primitive mesenchymal cell types (anglo- fibro- endothellomyo- and lipoblastomata) are found. The lessons are congenital deformaties of the ectoderm and mesoderm, and demonstrate a strong hereditary factor The individual with tuberous scierosis sedom lives more than so years, and in every instance there is present the previously described skin lesion in 80 per cent of the cases the renal neoplasm is present. In a smaller percentage there is an associated rhabdomyoms of the heart, fibromatom,

and malformation of other organs including the

skeletal system.

The author a patient was seen repeatedly during a 4 year period She had leasons of adenoma sebaceum and neurofibromatosis on her face back, and left fourth toe There was a marked cardiac systolic murmur and a large abdominal tumor on the right side. There were no other significant findings except a profound anemia. Intravenous pyelograms showed an enlarged and distorted right renal pelvis. There was no familial history of tuberous sclerosis although one sister was confined for insanity and a brother was treated for intense phobias the patient herself was somewhat unstable emotionally

The year before the patient was seen originally an exploratory celiotomy was done to ascertain the cause of fever abdominal tumor and anemia similar attack occurred a year later and the anemia on this occasion required the use of blood transfu

rious.

Three years later a similar attack of fever abdominal tumor, and anemia confined the patient to the hospital On this occasion the tumor seemed larger Another attack was experienced a year later and on this occasion the hydronephrosis showed progression along with elongation of the renal pelvis and calyces together with distortion suggesting hemorrhage. Upon nephrectomy the kidney substance was found to be almost completely replaced by various sized nodules of friable, grayish yellow tissue with nodules at the upper pole extending behind the liver The total weight of the kidney tumor was 1,400 grams. The tissue showed cytologically anencapsulated liposarcomas which were character itically slow growing and nonmetastasizing but there was local recurrence and in addition, renal parenchymal compression.

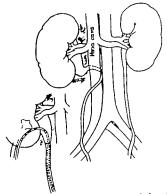

The postoperative course was complicated by a severe transfusion reaction but at present (2 years following nephrectomy) the patient is working and claims to have unusually good health

ROBERT LICH, JR., M D

Greene, L. F., and Kearns W M Circumcaval Ureter Report of a Case with a Consideration of the Preoperative Diagnosis and Successful Plastic Repair J Urol. Balt. 1946, 55 52

The authors report a case of circumcaval ureter this is the thirty third case reported the second preoperatively diagnosed and also the second suc cessfully repaired surgically although it was the fifth

in which such repair was attempted The patient was a 29 year old white male who had an attack of pain in the right costovertebral angle followed by the passage of urinary calcult a year prior to admission and then a recurrence of the pain 3 weeks before hospitalization Excretory urography demonstrated a right hydronephrosis with dilatation of the upper third of the ureter which ended abruptly and at this point there was a gentle curve of the weter with its convexity directed superiorly and medially the remainder of the ureter was normal.

Findings at operation Surgical repair shown in Fle inset

The operative findings and repair are depicted in Figure 1

The authors conclude that there is need of prolonged ureteral splinting after anastomosis of the ureter since in this case early removal of the splinting catheter was the cause of much concern, and the repeated introduction of ureteral catheters was nec essary in order to reduce and finally obliterate the extravasation present at the site of anastomosis The anastomotic site was splinted and drained for the greater part of 39 days postoperatively and the urnary infection was controlled by the use of one of the sulfonamides. Seven months after operation, at the time this article was written the urine was free of infection or any abnormality and the patient was asymptomatic. The kidney was almost normal, but ureteral dilatations at regular intervals were con-ROBERT LICH, JR M.D. sidered advisable

Soley P J : Ureteropelvic Obstructions in Children. J Urol Balt 1946 55 46.

Ureteral stricture was found once in 150 children when Campbell studied 10,000 routine autopsies. In 34 per cent of this group of children ureteropelvic obstructions were found and in 62 per cent ureterovesical obstructions. In another series of cases studied by Campbell and Bottomly the same rela tive proportion of stricture location was found and too a similar distribution was found in adults. The significance of aberrant vessels in ureteropelvic obstruction is controversial but the association of these vessels is not disputed

The symptoms of ureteropelvic obstruction in children are pain in the back and flank, gastroin

testinal disturbances a d the associated vestical furbances in the presence of pouria including hematuria. The finding of a flank tum risalite panal in fluctive of a poor prognosal ristoration of the involved kid of The laboratory tests for recal function were not found to portray accurately the end results following surgery. The author found that retrograde pevelographs with delayed emptying more accurately demonstrated the fewon than the firm station obtaid of with nirs.

venous urograms.

Treatment was discussed under two headings () ureteral dilatations in early lesions and (z) surgery when dilatations fauled. The purpose of surgery is to relieve obstruction and the coexisting infection. Uretropelvic obstructions are considered to be either of intrinsic or extrinsic etiology, the latter most commonly due to an aberrant versul. The fundamentals of surgical intervention are listanciased and the use of ureteral split ing catheters in

#### BLADDER, URETHRA AND PENIS

Weyds, R. The Treatment f Tumors of the Urinary Bladder in add Stockh 945 26 589

Weyde report 35 cases of bladder turn is treated from 192 to 0.92 at the N region Rad in Hopital, Oal Norsa. The verage age of the male patients was 5 care and that of the omen 60.4 verage, but eight patient had lecromolitating bladder care norms to had malignant papilloma to repullonation care norms and 55 were in such poor condition that the pallbatton treatment was not given

If the first 5 ro care afte the opening of the hospital primary roenting, therapy was usually employed although I see at this time the pain in would have received combined surgical and radio-logical treatment. It high roe tigen doses It this time the auth radm it is protracted force to consultradiation if field two frontial and two

back. If possible a t t l dove of at least 3 500 r administ red t each ti ld approximat h 150 r being given daily. At tal tumor dose of approximately 5,000 or or more is given with 175 ky. App-50 cm. PS. Il tance and 1 mm. Cu filter. A pre-enthe author dose evitoscopic lectrocoagulation celtro very small papillomatica. I tumors with narrow noninfiltrated peticles and bases. Larger tumors are coagulated openly through a cystotomy.

In young people with one or several small panillomas, cystoscopic coagulation is done and followed ty careful postoperative barryation. On young na tlents with larger and more widespread papillomas cystot my congulation and implantation of ra d um needles are performed. In middle aged and older people bladder papillomas are always treated as a carcinoma and the author's present method consists of cystotomy electrocongulation of the tumor implantation of radium needles in the wound bed and postoperative roentgen therapy as soon as the incision is healed. The author uses 10 mgm. radium el ment needles in 1 mm, of platinum from cm apart and attached to metal wires so that they may be removed in 24 hours. After the radium mplantation a menteen dose of from 7,200 to 4,840 divided on four fields is given Widespread tumors which are not removable through a cystot hay are given primary mentgen therapy and at times the tumor is so reduced | size that subsequent radical electrocoagulation and rad um implantation can be performed. No cystectomies have been per formed in this series.

The autho believe that in both papillom, articiona and in infiltrating carcinoma, rottine carcinoma and in infiltrating carcinoma, rottine control of the carcinoma and in infiltration to indicated, under the carcinoma attempted the use of the McCarthy resectances or it transarrelinal implantation of radium pecellar. Of the 1st patients, 11 are dead of carcinoma. Of 7 patients, 11 (14.3%) are byong symptom free after 5 years and 20 (8%) are symptom free after three carcinoma and 20 (8%) are symptom free after three carcinoma and 20 (8%) are symptom free after three carcinoma and 20 (8%). The Reservation, 110 m. Reservation, 110 m.

Lezarus, J. A. Primary Malignant Tumors of the Retrovesical Region, with Special Reference of Malignant Tumors of the Saminal Vesicies Report fa Case of Retrovesical Sarcoms. J Unit Balt. p46 55 90.

A case of primary acroms of th semnal vesicle are ported, with a critical review of the Interature IDe a shor states that only 3 cases of primary acroms of the semnal vesicle (including his own) and so cases of primary cardinoms of the semilar vesicle have appeared in the Interature Since cardioms of the prostate abows a tendency to mystel the seminal vesicles has a timo believes that only 7 of the semilar vesicles are accountly be listed as at theotic. In the remaining 13 cases the prostate was involved in the realignant process and it is therefore not possible t state with certainty that the lesion originated within a semilar vesicle.

The disease is most prevalent among aged men and the left seminal vesicle is involved slightly more frequently than the right. Urnary 35 mptoms rang ing from increased frequency to acute urnary retention were present in approximately 50 per cent of the cases in which the symptomatology was noted in the protocols.

Metastases in the regional lymph nodes the liver and the lungs were reported in 12 of the 20 cases. The mortality in this group was approximately 85

per cent.

Because of the inability in most instances to differentiate clearly between intrinsic tumors of the seminal vesicles and the tumors designated by loung as tumors of the retrovesical space the author believes that it is more correct to designate this group of tumors involving the seminal vesicles aspmany tumors of the retrovesical space

FREDERICK R. LIEBERTHAL M D

Leadbetter W. F. Repair of Complete Tear of the Membranous Urethra. Case Report and Suggested Tachnique for Operation J. Urol. Balt 1644, 54, 549.

During wartune tears or ruptures of the deep worker may be caused by penetrating wounds or fracture of the pelvis with displacement or separation of the pubic ram! The latter is the usual mechanism producing this Injury in civilan life Because of the provinity to other structures such as penas bladder and rectum more than one organ is commonly injured. As a general rule pelvic frac tures are also associated with other injuries and the

mortality is high

The diagnosis of complete tear of the membranou. urethra is simple if the possibility of it is borne in mind. There is usually slight meatus bleeding void ing is impossible if the tear is complete rectal examination reveals absence of the prostate from it normal position behind the symphysis Because of bleeding or the accumulation of urine and blood in in the space behind the symphysis a soft mas i felt filling this region. A sound or catheter pa sed into the urethra will be palpated after its passage through the triangular ligament directly beneath the rectal wall. The passage of a catheter does not result in the withdrawal of urine, though occarion ally some blood may appear. Once the diagnosis is made operation as soon as possible is necessary for the bladder will empty into the perivesical tissue-

The operation of choice is one which approximates the prostate to the triangular ligament and repairs the treiting channel. The penneal operation of carried out as a primary procedure acc mplish; this, Generally because of associated injunes in a supraphic cyatostomy is possible at this time and regalir of the urethra is left for a later date.

The author presents a report of the findings and treatment in the case of a 23 year old solder with complete division of the membranous urethra causer by a tank accident There was a complete tear of the membranous urethra a sociated with the creatment of the pubsic as well a multiple skeletal injuries. A primary cystostom was lone

Later it was found that the prostate had retracted after the injury the apex having been pulled upward and nointed backward toward the rectum vesical neck was elevated and pushed forward cavity existed between the two ends of the cut urethra. Some urine was passed rectally. I erineal operation was subsequently performed. The urethra was threaded upon a catheter throughout its lumen and the prostate was pulled down to the triangular beament by two heavy silk traction sutures through the prostatic substance on each side of the midline which were passed through the triangular beament and the perineal ti wes out on to the skin of the permeum toward the scrotum. The proximal ure thra was similarly brought forward with silk sutures brought out to the skin

Drought out to the skin. The author proposes a new operation which would accomplish primary reposition of the prostate and satisfactory apposition of the torn ends of the ure thra by the uprapubic route possibly to be done primarily at the time of the first injury. After threading the entire urethra over a Foley catheter the prostate is brought to the triangular ligament by silk traction sutures which are payed behind the symphysis directly through the perineal tissues laterally and through the perineal skin at the base of the scrotum. No attempt is made to repair the urether proper. I guide of some kind should be kept in the urethra lump healing until it is certain that instruments can be passed from below. This operation is suggested instead of simple cylorotomy.

DAVID ROSENBLOOM M D

Schourup & Pinstic Induration of the Penis

1cl ad of Stockh 1945 26 313

The pathology of plastic induration of the peniis obscure It can ist of the formation of a thick placue of fibrou ti ue in the tunica albugines of the dorsum penis and is probably caused by vascular changes Cartilage or bone is deposited in the lesion in about 10 per cent of the cases. The incidence of this condition is low (26 cases among to ooo genitournary patients reported by Aislin and 12 cases observed among 22 000 patients at the Radium Center in Copenhagen) The only certain fact I the association of this disease in many cases with Dupuytren's contracture which i also rare I en erally to per cent of the cases have been reported a ha ing both affections Hamann f und thi a socia tion in 23 per cent of his cases and the author in 40 per cent of the cases a resented in the article

The liagnost i rarely bubtful Ocea ionally restigenogram will help to how calcarcous deposits in the wall of the penus. I r the differential fragnost gumma gonortheal cavernitis, leucenia or tuberculou infiltrates and malignant tumors must be considered. They usually can be recognized by their location and the presence of ulcera

The medical and surgical treatment of this lisease a well a method of irradiation is discussed. The treatment of a cases is reported. Twelve wer

irradiated with x rays with from 500 to 2,000 r in fractionated does moderate filtration long distance and ahort distance arrangements varying with the case, and the testicles shielded 3 cases underwent surgery and 2 were both irradiated and operated upon. The results were as follows

Group Results	No. of
F lly setisfactory	3
Nearly satisfactory	3 4
Unsaturfactory N t followed up	4
Groups and 3 Results	No of Coton
Satisfactory	3
Less satisfactory Unsatisfactory	t

The principal beneficial effect was the alleviation of pain during erection which interfered with cohabitation

The author concludes that radiation therapy abould be attempted first the method of application being of minor importance and only if it falls should surgery be recommended

GERHART S. SCHWARZ, M.D.

#### GENTTAL ORGANS

Borthwick, W. M.: Tuberculosis of the Male Genital Tract. Gargen H. J. 1945, 44, 75.

The author's discussion of tuberculosis of the male genital tract is centered mainly on epididymitis. The age incidence is essentially that of the period of greatest sexual activity. Of 4 2 males with tuber culous epididymitis 88 32 per cent had at least one extragenital tuberculous lesion. He does not find that antecedent trauma or nontuberculous infection plays any significant role in the etiology of the discase. Diagnostic signs listed in increasing order of pathognomonic value are induration, enlargement and nodularity of the epididymis thickening of the vas deferens, involvement of the prostate and seminal vesicles, chronicity and bilaterality of the findings and tuberculous baciliuria. In the differ ential diagnosis gonorrhea syphilis, neoplasm non specific infection, epididymai cysts, trauma and torsion of the testis, and venous thrombosis of the pampiniform plexus must be excluded

Tuberculous epididymits was found to be blateral in 36.4 per cent of the author's cases in volvement of the tests was found in 35 st per cent, secretal fistulas appeared in 47 ot per cent, and pelvuc coincidental lesions were present in 87 st per cent. Sirty per cent of the patients suffering from tuberculous publishmits were known to have renal tuberculouis. It is beheved that the prestate is the link in the chain of infection between the kidney and the epididymits with the organisms reach the epididymis via the lumen of the was deferent.

The treatment of choice is surgical removal of the epididymis. When epididymectomy is performed, contralateral vasectomy is advised to prevent spread of the disease to the healthy side. The local prognosis is good but the general prognosis is that of generalized tuberculosis and is dependent upon conservative therapeutic measures and rest.

CLARENCE V HODGES, M.D.

Odegaard, H.: On the Treatment of Malignant Tumors of the Testis. Acts redial Stockh., 1045 15 445

In the 10 year period from 1976 to 1935 maller mant tumors of the testes in Norway knounted to only 0.3 per cent of the total deaths from cancer is only 0.3 per cent of the total deaths from cancer is men. From a practical clinical standpoint try may be divided into two main groups (1) sembons on the control of the cont

The usual treatment today is orthidectory with portoperative irradiation. It seems to be dear however from the various follow-up examinations published that rocatigen treatment of teratomas does not prolong life. On the other hand it is beyond doubt that rocatigen treatment of seminomas prolongs life. Himman has advocated a radical operation, i.e. removal of the lumbar lymph nodes on certain indications. He is of the option that patients with teratomas without claically demonstrable metastases should be subjected to radical operation and maintains that this operation is neither difficult nor dancerous.

If at the time of the orchidectomy lymph node metastases are not demonstrable, it probably does not matter whether the patient receives receipt therapy or not. In case of inclipient spread to regional lymph nodes one may perhaps have hope of destroying these metastases. On the other hand, if the seminoms metastases have become clinically demonstrable one must count on only a temporary innoversement.

At the Norwegian Radium Hospital, from 1935 up to and Including 1917 37 cases of malignant testicular tumors have been treated. Of these 31 were seminoona and 10 were malignant embryonal mixed tumors (teratomas). The oldest patient was 17 years of age, the youngest (with a teratoma) 1/9 years. In 19 cases the right, and in 18 cases the fit testis was affected. The 4archieon 2006 kets was carried out in 14 patients with seminomas (all with negative results) and in 1 patients with teratomas, (with a positive result in 1). The reaction was of so

prognostic value
Thirty-four of the 37 patients had been operated
on before admission to the hospital in 3 the condition was inoperable.

Nineteen patients with seminomas and 13 with teratomas have received adequate postoperative irradistion. Of the patients with seminomas, 11 survived and were free from recurrence for 2 years or more and 8 survived for 3 years or more 2 havelved for more than 5 years. Of the patients with teratoms, 4 lived free from recurrence for 2 years or more and 3 lived for 3 years or more. Prior to irradiation one of the survivors for 3 years (with a teratoms) was subjected to a radical operation (Hinmans) at which time metastases of the lymph nodes were found.

Nine patients died from metastases within from 2 to 23 months after admission to the hospital and 1 to 28 months after the onset of the symptoms.

JOSEPH K. NARAT M D

#### MISCELLANEOUS

Lazarus, J. A.: The Prevention and Treatment of Delayed Wound Healing and Ulcerative Cystitia following Surgery for Tuberculosis of the Genitourinary Tract J. Urel., Balt. 1946 55

The incidence of genitourinary tuberculosis has greatly declined within the past two decades.

Fostoperative fistula formation and wound dis integration are frequent complications following aephrectomy for tuberculosis

The ureteral stump plays a negligible role in the production of fistular

Singles are more apt to occur in the more acute forms of tuberculosis than in the chronic. A combination of deep x rs, treatment with ultraviolet radiation immediately following nephrectoms has almost completely eliminated this disagreeable complexation and has been found to be an extremely effective method of managing sinuses which are all ready present.

Of the 63 cases forming the basis of this clinical study 50.8 per cent revealed casvernous lesions of the kidneys removed 318 per cent py one phronis 8 per cent multiple abscesses and in 9 per cent the kidneys disclosed the lesions only when sectioned Bladder ulcerations were present in 63.8 per cent of the cases with casvernous tuberculosis of the kidney in 45 per cent of the cases of pyone phrosis in 100 per cent of multiple abscesses and in 66 6 per cent of the cases in which the kidneys showed lesions only when sectloned

The average number of x ray treatments given to patients with cavernous tuberculosis was 163 with pyonephrosis 136 with multiple abscesses 19 and with kidneys showing lesions when sectioned 167.

Deep roentgen therap) administered to the blad der is a distinct aid in alleviating bladder pain and in promoting the healing of tuberculous ulcerations

It is recommended that this type of treatment start immediately after operation since its greatest advantages are confined chiefly to the prevention of rather than the actual treatment of fistules already established.

Of the newer agents for the treatment of complicating cysitis following nephrectomy for tuber culosis the sulfonamides are highly recommended in all cases in which the unne from the bladder shows other organisms besides the mycobacterium of tuberculosis. Calcreose a derivative of creosote has been found helpful

A careful course of rigid hygiene similar to that employed in the treatment of pulmonary tuberculosis is mandatory in the postoperative management of all cases following operation

Lazarus, J. A.: The Prevention and Treatment of Delayed Wound Healing and Ulcerative Cyatitis following Surgery for Tuberculosis of the Genitourinary Tract. J. Urol. Balt. 1946 55

The incidence of genutourinary tuberculosis has greatly declined within the past two decades

Postoperative fistula formation and wound disintegration are frequent complications following aephrectomy for tuberculosis

The ureteral stump plays a negligible role in the production of fistulas

Sinuses are more apt to occur in the more acute forms of tuberculosis than in the chronic. A combination of deep x ray treatment with ultravolet radiation immediately following nephrectoms has almost completely eliminated this disagreeable complication, and has been found to be an extremely effective method of managing sinuses which are already present.

Of the 63 cases forming the basis of this clinical study 50 8 per cent revealed cavernous lesions of the kidneys removed 31 8 per cent pyonephrosis 8 per cent multiple abscesses and in 9 per cent the kidneys disclosed the lesions only when sectioned Bladder ulcerations were present in 63 8 per cent of the cases with cavernous tuberculosis of the kidneys in 45 per cent of the cases of pyonephrosis in 100 per cent of multiple abscesses and in 66 6 per cent of the cases in which the kidneys showed lesions only when sectioned

The average number of x ray treatments given to patients with cavernous tuberculosis was 163 with pyonephrosis 136 with multiple abscesses 19 and with kidneys showing lesions when sectioned 167

Deep roentgen therapy administered to the blad der is a distinct aid in alleviating bladder pain and in promoting the healing of tuberculous ulcerations

It is recommended that this type of treatment start immediately after operation since its greatest advantages are confined chiefly to the prevention of rather than the actual treatment of fistulas already established

Of the newer agents for the treatment of complicating existis following nephrectomy for tuber culous the sulfonamides are highly recommended in all cases in which the urine from the bladder shows other organisms besides the mycobacterium of tuberculosis. Calcrose a derivative of creosote, has been found helpful.

A careful course of rigid hygiene similar to that employed in the treatment of pulmonary tuberculosis is mandatory in the postoperative management of all cases following operation

## SURGERY OF THE BONES JOINTS MUSCLES, TENDONS

CONDITIONS OF THE BOXES, IGINTS. MUSCLES, TEXTOURS, RTC.

Summey T. J., and Pressly C. L.: Sercoma Complicating Paget a Disease f Bone Ann 7 c 046, 23 35

Sir lames Paget in 1842 saw the first nations with the disease which he later described a cateltia Ultogether he saw 23 cases and his classic description of this spongs hypertrophy of bone i still unsurpassed. It begins n m ddle ace or later is very slow in progress and may give no other troubles than those which are due to the change of shape size and direction of the diseased affects most frequently the long bones of the lower extremity and the skull and is usually symmetrical. The bones enlarge and soften those bearing weight yield and become unnaturall-curved and missbanen. The sp. c. may sink and but the imbs however seem t shorten mrshapen remai strong l bt to pport the

Aurehow suggested leontuses osses as a name for the cases in which the disease is limited to the shall and facial bones. Early in the disease wh n the connective tissue

has replaced much of the oriental bone, there is bow ing of the softened weight bearing bones. As cancel. lous bone is subsequently in didow in large amounts the cortices become thick and hard and the typical mosale pattern f lamella develops with fibrous tesue replacing the marro

The cause is till k n but the original acceptance of a chronic flammation tend to be replaced by the concentio of some endocrine cause the narathyroid seeming to be the most probable offender. Serum alkal ne phosphate is high but as vet no other blochemical findings contribute to a

solution. Since many cases I Paget disease are relatively a ymptomatic the ocidence rat is dependent upon the extent of the routine mentgenological studies. and may be as high in 600 patients Eight of Paget s 23 pat t died hil nde observation (t of mallgnant less n ) and this tendency has been emphasized by ma student Sarcomatous d reperation of bones P get I sease is fou d in from 5 t 4 pe ce t of the patients according to most authors. The few h question this high per centage still admit a great r incidence than in the general populat on

The predisposing fact remains a most question, but Jaffe a belief that the trem indous p oliferative capacity of the tusue involved in polyostotic Paget a disease may n stielf be th basic atimulus for tumor formation seems most reasonable. The multiple bone involvement when scera are spared lends further credence t this idea. The incidence of osteitis deformans is greatest patients in re than

40 years of age with males apparently predominating among both the cases of the basic disease and those with complication sarcoms.

To 73 cases of sarcoma complicating Paret a decase collected from the literature, the authors have added their own a cases. Localization of the sarrows favors the femur humerus skull and tible, in that order and the scapula vertebra, and flown next most frequently. The prospess is grave for there is no known cure Early amputation with or without previous roentgen therapy is the treatment of choice and roentgen therapy alone may be pulliative in the terminal stages.

The 3 new cases are presented with illustrative toent renorrams and photomicrographs, which established the diagnosis confirmed at autonsy \ complete bibliography is included

Diez. B. R.: Chronic Tuberculous Synositis of the Wrist (Sino itis cronicas tuberculosas de la mo-neca) Rev A med argent 1945, 59 1 7

cases reported were of the author's own personal experience and are presented became chronic tuberculous synovitis of the wrist does not seem to have been previously reported in the Argen timan medical literature also, several aspects of the author's experience seem worthy of special notice The first was that of a robust officer of the maritime service in whom the bursae of all the tendons on the dorsal and lateral aspects of the left wrut had become progressively involved in a painless swelling with il ctuation and rice grain semation following a blow over this point 5 years previously The second case was that of a woman of 22 years with a similar history except that there was no known traums and the process involved both wrists. In her case the duration of the condition was a years

The operation was essentially under Kulenkamps brachial plexus anesthesia in the first case and under erve trunk and peripheral infiltration with novocain ( o'c) in the second An incision was made down the middle of the back of the wrist and skin flaps were held back on each side the posterior an ular liga ment of the wrist (ligamentum carpi dorsale) was incised with apparently a separate incision made d rectly int each osteohbrous compartment. Each bursa was carefully desected free down t its attach-

ment to the tendon itself In loosening the burse from the bgament, that por

tion of the latter which seems badly diseased may be cut away with the bursa, to leave only sufficient teadon substance to assure continuity or if the ligament has lost its continuity it may be reunited by a suture r by tendon transplantation it will usually reconstruct itself. An attempt may be made to reconstruct the esteofibrous compartment, although this again seems to be optional as the posterior annular ligament also shows a tendency to reconstitute itself. The wound surfaces were powdered with lodoform and the skin was sutured to leave merely fillform dribage. The part was put up on a posterior plaster splint for from 8 days to 2 weeks when the stitches and drain were removed and the splint was reapplied with however daily sessions of mobilization of the fingers.

Rich and abundant food vitamins and calcium were provided and in the second case the condition of the other wrist improved so much following the operation that the projected operation for this wrist was not required

The author's experience gives one the impression that the lesion reported might be susceptible to tuberculin therapy John W. Brenn M. D.

Kjelland, P. M.: A Rare Anomaly in the Elbow. Acta radiol. Stockh. 1945, 26, 491

The author presents two cases of patella of the elbow joint.

The first case was that of a washer woman 51 years of age. She suffered two minor injuries to the left elbow one when a small child and the other at the age of an outliner of which was treated medically. She also had rheumatism for many years but with out particular localization to the left elbow. The recent study was brought about by a slight injury to

the left elbow 4 days prior to the examination Roentgenograms of the left elbow in various views and under different angles revealed what appeared to be a patella of the elbow joint. Under fluoroscopic control this accessory bone was found to move with the electanon from maximum flexion to the mid position then from the midposition to maximum The upper pole moved forward and finally came to rest with the axis of the patella per pendicular to the axis of the ulna (Fig. 1) Injection of the elbow joint with 20 per cent perabrodil revesled that the contrast medium entered between the electron and the anterior aspect of the patella. which seemingly was covered with cartilage. In addition there was evidence in this case of arthrosis deformans.

The second case that of a 73 year old man without a history of previous injury arrived for examination because of rheumatic pain in the left elbow over a period of several years. Roentgenograms revealed a clesion that shaped accessory bone with a slight con cave anterior surface just above the olecranon which way thought to represent a patella of the elbow.

In connection with these a cases the author revened the medical literature. He was able to collect 15 additional cases. In 11 the disgnost appeared certain in the remaining 1, doubtful in the misjority the extension of the elbow was impaired and during movement the bone turned into the fosas of the observation as if there was a joint between the posterior surface of the observation and the anterior surface of the patella. The posterior the incepts ligament. Several of the cases re-

the traces ligament is attached the smooth anterior surface which is probably covered with cartilage. Arthrosis de formans, 3 different phases of the joint inovenent.

viewed showed in addition, characteristic changes of arthrosis deformans. It must therefore be assumed that elbow joints with patellae are predisposed for this affection. Otherwise the symptoms are few and patients afflicted with it are able to work.

The etiology 1 not altogether clear. The author prefers to assume an embryonic origin for several reasons. It is known that the olecranon sometimes has two points of osubcation, one of these develops into the olectanon process of the ulna and the other into an accessory electanon. By the same mechan usin the second point of ossification may develop into a patella of the elbow joint. The origin from a pseudarthrotically healed olecranon fracture as advocated by others is contradicted by the fact that in only 2 of the reviewed cases was there evidence of definite trauma. Moreover in a cases the condition occurred bilaterally and in a instance it was found in father and son | finally there is ample proof that patella of the elbow joint is encountered in the animal kingdom a for example in frogs and lizards in birds bats insect caters rodents and one of the edentates T LEUCUTIA M D

Lapidus, P W Spastic Fintfoot J Bone Sug

Painful so-called pastic rigid or contracted flattoot is a clinical entity vaguely described in most textbook. Most investigators have believed that the cin litton is an advanced phase of flaceful flatfoot wherein faults mechanics set up a reflex apastm of the ji nat is because if irritation in the jubilar region.

A review of the literature presents no more apteoned in on than those voiced by Todd who offers a concise summary of the present state of our ign rance and agrices with the present author a belief that treatment. It he spasm also he is not rational, box m is not the disease but the rould of the disease and manupulation with immobilization in varus is not pitywoological, the valgus possibly being a post it no frest for the involved joint.

It is generally agreed that the condition is painful with spann limited to the promator group. Trauma or occupational strain is noted appreciably often. The onest frequently occurs during adolescence. The incidence is alight compared to the large number of facerd flattect seen. There are various interpretations of the facts that per planns is not always present and that a normal or even caves condition of the longitudinal arch may concur. Tenderness has been noted both on the lateral and medial aspects of the foot. The role of arthritis of the subtalar iont is variable.

The author presents the auatomy and mechanics of the subtain ploin graphically and gives a logical explanation for the pronator spasm. Any lesion of the interessours talocalcancel ligament, regardless of etiology may induce the syndrome appropriately called spastic substair lesion. The substair loint surfaces may or may not be involved and per planus in our necessarily a part of the syndrome.

The author classifies cases of the disorder according to the extent of the pathological changes, and outlines the treatment appropriate for each type. Drastic procedures aimed at the elimination of pronator spasm are unsound and often dangerous.

FRANCES E. BEFENEURE, M.D.

#### SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Higgs, S. L.: The Use f Cancellous Chips in Bone Grafting J Bone Surg 946 25 5.

Screnty-one consecutive cases of bone grating were reviewed by the author 60 of which were operations for nonunon of the long bones. Among recognitions for nonunon of the long bones. Among no recognition of the long bones and cortical grafts plus cancelloss chips were used in most cases. All of the operations resulted in an union, although in 4 patients reoperations was required.

The r other cases were esteoclastomas solitary cysts and outcitis fibrosa cystica, and arthrodeses, in all of which cancellous chips were used to fill the

bone defects.

For successful use of cancellous chips, rigid first too is necessary. The autho has used a screwed-on only graft for the humerus, an onley or inlay for the radius and ulna, a sliding inlay or onlay from the other ley for the tibla, and a screwed-on onlay graft for the femur.

Scienced bone must be removed as well as all scarred and fibrous tissue. Bare muscles should be brought in contact with the bone whenever possible Skin grafting may be necessary

Despite the fact that many of the cases had recently been septic, bone grafting was done. Peni cillin and sulfanilamkie powder were applied.

Bone chips hasten the time of union by approximately 5 per cent. The chips with cortical grafts add in filling gaps in the long bones and defects in cysts and in filling gaps and crevices in arthrodesin operations. Design M. LYDPIRGU, M.D. DARGE H. LYDPIRGU, M.D.

Ernst J: Canalization of the Femoral Epiphysis According to Duvernay (Le forage de l'epiphysis fémorale de Duvernay) Acta radiol. Stockh. 1943, 20, 76

Divernay popularized drilling of the femoral epiphysis as the method of treating arthrosis of the hip For this purpose he uses a drill 6 mm. in diam eter which makes a channel through the femoral

neck and head.

Contradictory opinions regarding the mode of action of the operation have been advanced by various authors. Some claim that the procedure is followed by a diministion of the hyperemia which is responsible for narefaction of the bone. This hypothesis is based on oscillometric measurements which show larger excursions before than after the opera

tion. Others maintain that the hyperemia following the operation produces granulations of the boay structures. This result is compared with the sequelaof drilling the bone in cases of pseudarthrosis. Results of the operation reported by vancus authors differ to a great extent. This may be due to

authors differ to a great extent. This may be due to variations in the length of observation or to differ ences in the pathological conditions. From the anatomopathological point of wive some written differentiate two types of arthrowin of the hips (t) the science-oatomytric type in which sciencide bose tissue and crysts are found (this type has a slow evolution and llimitation of motion is more pronunced than pain) (s) the type which is characterized by atrophic alterations and rarefaction. In the latter type osteophyric formations are oft, and the osseous rarefaction and formation of cysts are marked. The cysts contrary, to those in the first type are not surrounded by sciencid tissue they are soft and compressible. The lesions develop rapidly and cause much pain. This type of arthrows yields the best results after drillips.

The author performed canalization of the femonipiphris at times in 39 patients 1 of whom were treated on both sides. The drill used was 5 mm in diameter. In the majority of the caveral canals, up to 8, were drilled the average number beling 5 or 4. Of the 44 operations 19 were done in womes and 32 in mm. The Irsion was present on the right side in 35 instances and on the left side in id. The ages of 19 patients ranged from 5 to 60 years of 1, row of 61 to 19 years of 6 from 41 to 5 years of 1, row of 10 40 years and of 2 from 11 to 80 years. The dors tion of symptoms in 5 of the patient exceeded 5 years. In 35 cases the condition was primary fidepatific, and in 8 it was secondary following a competition of the light fracture of the femonia need, congenital

As to the complications, 2 patients developed a hematoms, 2 developed philebits, 1 poeumonis, and 1 paresis of the peroneus muscle. In 4 patients a tenotomy of the adductor muscle was performed immediately following the drilling or a few days

dislocation, o cora vara.

A follow p of 6 months after the operation showed the condition to be improved in 76.4 per cent and anchanged in 23 6 per cent the respective figures after two years were 70 1 and 29 0 per cent, and after six years 64 3 and 35 7 per cent, respectively. After six years 63 6 per cent of the patients had no plan at all, while in the remaining 9 7 per cent of improved cases the amelioration was partial as far as pain and limitation of motion were concerned.

In case favorably influenced by the operation the cyts and ossour surfaction subsided to a great extent, being replaced by a solid tissue while in case in which failure was recorded, sometimes an increase of the number of cysts and rarefaction of box were found. The operation apparently was not followed by a diminution of the estephylic forms ton or decrease of deformity of the femoral head in other groups.

#### PRACTURES AND DISLOCATIONS

De Luca, G., and Farina, M. G.: The Treatment of Compound Fracture and the Closed Plaster Method (La cura delle fratture esposte ed il metodo degli apparecchi genati chiusi). Polidin. (see prot.) 1945 52, 402.

The closed plaster method used by the authors in both civilian and military practice for compound fracture is essentially that developed by Orr and later by Trueta, the circular plaster cast being spiled directly to the skin according to the principles hid down by Boehler following the first World War.

In the authors own material consisting of 1,886 open fractures 151 cases occurred in civilian life and 1735 were due to war. The closed plaster method was used in 137 civilians (90 per cent) and in 1,320 soldiers (76 per cent) In civilian practice good results were obtained with this method in 78 per cent of cases mediocre results in 10 per cent, and poor results in 11 per cent in military practice good results were obtained in 73 per cent mediocre results in 12 per cent, and poor results in 15 per cent. How ever the alightly higher percentage of unsatisfactory results in military practice is not a fair comparison because of the higher percentage of serious fractures for instance there were four times as many leg frac tures as those of the femur in civilian patients while in the military material fractures of the femur predominated markedly Primary soft tissue suture could be done in 112 of the civilian patients, but was not attempted in the war material. In civilian prac tice there was not I instance of gas gangrene or of tetaqus while there was a single example of each in the war material

The case with tetanus an open fracture of the lower ibid of the right leg was of especial interest in that the patient was erroneously twice given tetanus autitorin on succeeding days immediately after the fluory on the tenth day there were clear indications of tetanus infection, which however disspected under the usual therapy.

The authors primary treatment of the wound which they call mechanical sterilization and which

they seem to dutinguals from excession of the wound, consists of freeing the wound from blood clots, all foreign material, and devitalized tissues especially muscle tissue and detached bone splinters. It is initiated—if the condition of the patient permits—under intravenous eunarcon anesthesia after 1 or 2 hours in order that the patient may reuperate from any initial shock an attempt is made to bring the blood pressure to about 170/65, and diagnostic or other manipulations of the uljured part are kept to the minimum. At this time an attempt should be made to appose the bone fragments before they are incased in the plaster and even in the cleanest wound pethaps with primary suture sulfa drugs should often be insufficied into the wound.

The surgeon must first be assured of the vitality of the limb with extension in a Thomas or Braun splint (perhaps for a few hours at first) and close watch must be maintained at all times during the succeeding days. In fact, it may at times prove hazardous to enclose the limb of a wounded man in plaster in wartime if he must be transported immediately and transferred to the care of other surgeons who may not be aware of the limportance of the lesion

JOHN W BRITHMAN M.D.

Kirby C. K. and Fitts, W. T., Jr: The Incidence of Complications in the Use of Transfizion Pins and Wires for Skeletal Traction Ass. Sur., 1946 183 27

At a General Hospital in India, 342 transfixation pins and wires (195 Kirschner wires 95 Stelmann pins and 52 Roger Anderson pins) were used in the treatment of 233 fractures of the long bones. Three hundred and five pins and wires were observed during the entire period of their use and were removed at the hospital.

Among the 30s transfixtions there were 12 complications as follows soft ussue infection without esteemychius or the formation of a chronic draining sinus at the site of a Steinmann pin loosening of 4. Kirschner wires loosening of 3. Roger Anderson pins 2 cases of transient peroneal nerve palsy breaking of 1. Kirschner wire and alipping of 1. Kirschner wire bow. It is believed that the last 11 complications were avoidable, and in no case did a complication have any significant effect upon the course of treatment or the final result. The final results of treatment are not described in the article.

After an observation period of from 5 to 6 weeks there were no complications in the 37 transfirtions in which the final result was unknown Prophylactic oral sulfonamides were administered to approximately 60 per cent of the patients either because the fracture was compound or because of associated injury or disease and no infection developed in this group. Since infection occurred in only 1 of the 40 per cent of patients who had not received sulform mides and it is not at all certain that a sulfonamide would have prevented this infection, there is no statistical evidence that prophylactic sulfonamides played a part in preventing infection at the pin site.

in this series. In no instance was a prophylactic sulfonamide used for the sole purpose of preventing infection at the pin site.

CRARLES A. WALTMAN M.D.

Robertson R. G., Cawley J J., Jr., and Faris, A.M : The Treatment of Fracture Dislocation of the Interphalangeal Joints of the Hand, J Bees Surg. 046 a8 68

Fracture dislocation of an interphalangeal joint of the hand is an uncommon lipity and in the absence of adequate treatment results in severe permanent disability. Reduction is difficult to maintain by conservative methods of splinting, because of pressure necrosis of the soft tissues and the authors recommend a method of multiple skeletal traction which they employed successfully in the treatment.

of 7 cases of this type.

The finger is prepared for surgery and is covered with a sterile dressing A plaster-of Paris cast is applied from the proximal palmar crease high onto the forcarm and a wire banjo splint is incorporated in the desired position Under general or local anesthesia a small kirschner wire is inserted transversely through the neck of the phalanz proximal to the dislocation and another wire is placed transversely through the base of the phalanx distal to the dislocation. A third wire is passed transversely through the neck of the middle phalanx if the infury involves the proximal interphalangeal joint. If the distal interphalangeal joint is involved the third were is passed transversely or vertically through the distal phalanz. A small temporary dressing is applied about each protruding wire. The wire is then cut and fashioned to form a traction bow. To each of the bows a rubber band is attached and fixed to the banko The involved joint is then flexed to from so to to degrees and the desired traction is applied to each band at such an angle as to secure reduction of the displacement.

In the 7 cases treated by the authors the shortest period of traction fixino was 2 days and the longest was 3 odays. There were no operative infections and excellent functional results were obtained All 7 cases reported were caused by the patients being struck on the end of the extended finger by a baceball or softball. Custants A Watarous, M.D.

Soto-Hall, R., and Horwitz, T: Compound Fractures of the Femur J Am M Arr 946, 3

The late results of treatment of femoral fractures are reviewed in an attempt to throw light on the elikelogy of such complicating factors as separa monumon deformity and knee stiffness. The series includes 1 y compound fractures of which y had been treated by early internal fixation. To obtain the proper standard for comparative study, 46 simple fractures are included of which 14 had been treated by early internal fixation.

A very high proportion (20%) of compound fractures without internal fixation healed without

sepsis. When this group is added to the 44 per crut classified as mild infections because they represented mainly soft tissue sepsis and healed within 2 to 3 months, the whole picture presents a brilliant achievement of war surgery

The infected fractures (17%) include many case of extensive loss of soft and bony times with vascular damage in which septis is almost unavoidable. In cases treated by early internal firstion through an open wound, the incidence of severe septis was about 50 per cent higher than in patients treated without metal firstion. In the cases of most of there men the plates or metal had to be removed. In some cases severe infection appeared to be under control for several weeks while chemotherapy was being administered later the infection became clinically evident.

The following procedure seemed to offer the least danger for the type of fracture in which internal

fixation appeared indicated

A thorough definitement was done early, and was followed by delayed closure of the wound from 7 to days later. After the ordinal wound had bealed in an average of 6 days the fragments were appointed to the control of the control of

Chemotherapy included the use of penkillin or a sulfonantife compound, or both The findings cofirm the fact that modern antibacterial agents may 
produce excellent results in the control of lafection 
and in the reduction of complications, but that they 
are impotent in the presence of tissue which has lost 
its blood supply and which does not allow the drug 
to come in counter with the infection

Cases in which union occurred within a period of from 5 to 7 months were classified as delayed union cases showing neither clinical nor radiological evi d nee of bone union beyond 7 months were classified as having reached the stage of nonunion. Conaldering the frequency of severe injury with com minution and absence of bone fragments, the proportion of bone union which occurred in cases treated by external splinting was extremely high 86 per cent and definitely higher than the finding in fractures treated by internal fixation. A comparison of the time required f r union in simple fractures treated by open and by closed methods demonstrates that in spite of the improved apposition of fragments in the open cases, there was little difference in the period eeded for bone healing. The state of delayed union and of nonunion appears directly related to the degree of bone loss or dam age distraction and the presence of infection. Distraction even of a very minimal amount, is particularly harmful.

A comparison of the results with respect to retoration of knee motion in men treated by internafixation and in men treated by traction showed no appreciable difference. The indungs were not en tirely conclusive because in a number of patients who had had sepsis or delayed union the splinting and man made sectors of decayed union the spinitums had been too recent. The average period from the date of injury to the last examination was only 91/2 months so that the statistics do not indicate the final result but do describe the slowness in restora and result but to describe the slowless in restorato be definitely helpful were the use of resistive exercises and the use of delayed closure Successful delayed closure resulted in much earlier healing and les scaring so that exercise and activity could be An important disability was a hmitation of extension of from 5 to 10 degrees in about one-third of the cases This disability could be overcome after several weeks of active exercise, but its occurrence argues in favor of treatment of fractures above the lower third with the knee in full extension

Other complications were refracture in 5 patients

The authors conclude that early and adequate de and renal lithiasis in 6 patients brodement is the most vital factor in the successful treatment of compound wounds and that conserva the treatment of traction in balanced suspension gives extremely gratifying results Joint L. Lindquist M D

King, T : Slowness and Failure of Bony Union after Fractures and Osteotomies of the Proximal or Trochanteric End of the Femur Assiral N Zeeland J Surg., 1945 15 33

Nonunion is very rare in extracapsular lateral or intertrochanteric fractures of the femoral neck and low union is the rule. In the past 10 years the athor has seen only 2 cases of nonunion of fractures if these types. Prolonged immobilization provokes complications and difficult nursing problems which may be obviated by internal fixation by the Blount and Moore blade apparatus the nail and plate method of Jewett or Hawley and other similar methods. In addition more rapid osseous union realls because of good reduction firm apposition of the fractured surfaces and absolute immobilization The Stader or any other form of splinting which requires that the bones be transfixed by 17 inch nais above and below the fracture site and attached to some form of external holding apparatus is considered ered too dangerous because of the infection along the pur that must inevitably occur in a certain propor

Fractures at the base of the neck and between the to of the greater trochanter and lesser trochanter tion of cases. can be treated with the Smith-Petersen nail and no supplementary plate is required. When the fracture is situated distal to the level of the lesser trochanter a plate is attached to the Smith Petersen nail. In the reduction of fractures of this type, coxe were should be overcome on the orthopedic table by traction and abduction but the external rotation that is present in most cases should not be corrected by internal rotation of the limb as is carried out in intracapsular fractures Accurate reduction is ob-

tained by allowing the limb distal to the fracture to remain externally rotated about 45 degrees from the vertical plane and thereafter correcting any dif ferences in the angles of rotation between the frac tured fragments by pulling forward the trochanteric fragment with a sharp hook. When the nall is introduced the angle of declination is forward from 25 to 15 degrees instead of backward At least 1 to 11/2 15 ucgreen material of backward art reast 1 to 175 inches of the head end of the nail should stand out before the plate is attached, as it will be impossible to attach the plate if the nail is driven all the way in A modified Hawley plate with a reamed ring is used and is attached to the tapered head of the nail. It provides a strong fitting especially when fixed down by the screw When the angle between the plate and reamed ring is to be altered so the plate is parallel with the femoral shaft another taper headed remains with the semona share amother taper nestern nail should be used for the adjustment while the plate is held in a sterile towel. Levers, pliers, or vises should not be used to alter this angle as they may convert the absolute circle of the reamed ring into a slight ellipse and thereafter it will not be possible to attach the ring to the tapered nail head

Seven cases of nonunion among 120 subtrochanteric estectomies are reported and summarized according to Table I Three cases were treated by bone graiting. The pelvis is raised 6 inches from the operating table with sand bags. At least half of the operating table with said ones. At least than or the illac crest and adjacent thum should be removed to obtain a sufficient amount of bone for packing the ununited bone area. The site of nonunion is approached by an incision that is somewhat more anterior than the usual lateral one After the bone is exposed by cutting through the tensor fascis m exposed by cutting through the tempor inserts femoris and vastus lateralls muscles, a curved lever is placed medial to the femoral shaft and just below the base of the calcar femorale in the region of the lesser trochanter Thereby the nonunion area is seen from the front. A 1/2 inch gouge is used to cut a gut ter in the bone proximal and distal to the ununited area and this gutter should be as large as possible The gouge is driven deeply into both fragments so that bleeding cancellous bone is exposed. The fresh bone obtained from the ilium is chopped into small pieces no larger than mause. The chopped up bone is hammered into the medullary cavities of both fragments of the nonunited bone with the blunt and round head of a chisel until it forms a paste. After that the bone is packed in front and to the lateral side Finally any respectable looking bone that had been cut out of the ununited area for providing the gutter is chopped up into chips about the sire of gutter is chopped up into chips about the sire of wheat grains and inserted. When the wound is wheat grains and inserted. closed a bulge should be evident on the surface, indicating that a large mass of bone gratung material lies underneath. Immobilization is done by means of plaster spica or with the sling and traction All 3 patients of erated upon obtained sound osseous

The method was also used successfully in the treat ment of a patt nt with nonunion following a fracture of the upper femoral shaft a trochanteric fracture

TABLE L-ANALYSIS OF SEVEN PATIENTS WITH NOVUNION OUT OF ONE HUNDRED AND
TWENTY SUBTROCHANTERIC OSTEOTOMIES

( ) Wheety patients were immeditured by aline and traction, and so in large phaster spices ( ) There were y patients with necession, and a of the land been immediated by sing and tracted and 3 by plaster spices ( ) Three of the y patients with nominion were operated upon by been graften

In the presence of infection an advantage of this type of bone graft is claimed over the tibial twin aw har of bone because the entire graft in on prome to be lost. Case 6 had a sinus which could not be cleared up. If was excised at the operation and the spongoes graft was employed. Infection supervened, but osseous union resulted after 6 months. When spongoes graft for sommlone is combined with nailling and plating the nail and plate are attached into the first type that the functure site and not on the lateral sepect. A complete freeing of the two nonnunted ends is unnecessary it takes too long and a harmful because it results in a disturbance of the blood rapple.

Internal fixation of the osteotomized fragments after subtreelsnetter osterotomy by nafling and plating eliminates external politting and the patient may be ambiant or at least free to move around in bed. Before the operation, the exact site line, and angle of the osteotomy must be planned because of the bends and angles that must be made in the platent to conform to the osteotomy. These details are worked out with paper models made from tracing of the x-rays. The plate is bent by the surpocal

maker to the shape required because the steel mort be hesited for bendling. The plating of a Lorent McMurray outcomey is fairly easy if the plate is bent beforehand and the orteotomy is performed to plan but the Schams operation is more difficult unless the upper fragment can be hooked down into the adducted pointom. Hit cannot, then the growth fully abducted below the site of outcolorny which will make the application of the plate rather dif-

which the displacement of catestomy has been abstituted by some surgeons for nailing of late anymaic fractures of the femoral neck to eliminate according to resting the complications should be process. The author surgeous complications should they occur. The author surgeous complications should they occur be not been supported by the fracture is more than 3 weeks old, the bone is comminated, or the patient is a young manual laborer. No cases utilizing this form of treatment are reported.

This article is well illustrated with diagrams and x rays. A short bibliography is appended CRARIES A. WAIDERS, M.D.

### SURGERY OF THE BLOOD AND LYMPH SYSTEMS

#### BLOOD VESSELS

#### Ross, J. P.; The Surgery of Arterial Disease and Injury Brit M. J., 1046, 1, 1

Vascapastic phenomena are seen in a vanety of conditions but true Raymaud's disease is a clinical entity. It is characterized by color changes in the digits produced by cold and occurring in attacks which show a rapid onset and recovery the extrem lies are affected symetrically. The peripheral pulses are preserved, and if there is any loss of tissue it is never more than a shallow ulceration close to the facetups true gangrene is extremely rare. The condition is almost exclusively limited to females is, not commonly excited by emotion and is not usually succeed with excessive sweating. The author spress with Lewis that it is due to abnormal sensitivity to local cooling of the small arteres.

In an attack the lumen of the digital arteries as aboost completely obliterated. The value of sympathetic denervation is that the lumen of the vessels as the complete of a greatly does not arest the circu taken completely. Since sympathetic may should be complete for satisfactory results the author favors the posterior approach of Smithwick and White for the upper thoracic chain. With the anterior approach of Telford there is greater danger of sparing sationizally shonormal finaments. For the lower extremity removal of the second third and fourth lumbar symples as the sure those of the contractions.

lumbar ganglia is the usual procedure

While there are many different causes of obliter ative arteritis it is the level of the block in the ar tenal tree not the cause which determines the clin ical picture and the value of sympathectomy in its treatment. Three clinical groups may be recognized In one a main vessel, such as the femoral or popli test artery is thrombosed and the presenting symptom is intermittent claudication in the call muscles The nutrition of the skin of the foot remains good since an adequate collateral circulation keeps the distal vessels supplied. If the level of the block is low enough to involve the sural arteries which supply the gastrocnemii sympathectomy is of little value for claudication. However if the block is more proximal sympathectomy will provide a consider able increase in the blood flow to the calf For this reason it is important to palpate the femoral and popliteal pulses as well as those in the ankle

Some information about the probable effect of synchrotic denervation may be obtained by tem porary block of the sympathetic trunk. A good exposse is an argument in favor of operation. On he other hand a poor response is not sufficient to key the patient possible relief by sympathectomy ince the postoperative improvement is gradual

In the second clinical group the distal arteries are uncipally affected and the characteristic manifestations are rest pain and nutritional changes in the skin of the foot. The pulse in the main vessels may be present even at the ankle but there is an abrupt drop in the surface temperature at the level of the arterial obstruction. Sympathectomy in this group may often abolish the intense pain and permit successful local amputation of the toes if gangrene has already been established

In the third group there is widespread narrowing of the lumen throughout the arterial tree. Sympath ectomy is generally useless and amoutation above

the knee becomes necessary

Fresh lacerations of the arteries should be repaired when possible, but contusions should be treated by excusion of the contused segment and ligation of the companion vein. When an arteriovenous fistula follows vascular injury quadruple ligation and excusion is the usual operative procedure Twice in cases of popliteal aneurysmal varix the vein was ligated above and below the fixtula so that the latter could be isolated and heated like an arterial branch. The main artery was preserved. These patients suffered from symptoms of venous obstruction afterward. Consequently, in 2 other cases the artery was ligated above and below the fistula but the vein was left intact the results were most satisfactory in these a patients. Because of the abundant collateral circulation associated with arteriovenous fistulas it is advantageous to preserve the vein when it is feasible to do so

THEODORE B MASSELL, M.D.

#### BLOOD TRANSFILSION

#### Iokhveds, B. I. Intracardiac Blood Transfusion Am. Rev Seriet M. 1945 111 116

The author reports 2 cases in which a physiological solution of sodium chloride glucose, and blood were used for restarting the intracardiac blood flow

In the first case the transfusion of blood through a needle inserted into the right ventricle corrected the apparent or clinical death and restored consciousness. Severe myocardial damage was probably responsible for the irreversible death that occurred 31/4 hours later. It should be emphasized that in apite of the marked flabbiness of the myocardium the needle which was present in the heart for about 15 minutes while the heart was contracting had left only a minute puncture.

In the second case the cause of collapse and clinical death may be attributed to the profuse hemor hage and to the rapid blood loss. A reflex shock occurred the volume of the circulating blood decreasing even more and the flow of blood to the heart diminishing greatly. Application of massage to the heart externally and the intracardiac injection of epinephrine might be insufficient in such cases ance the cause of death is not failure of the myo-

cartium but Inadequacy of the blood supply to It. The heart even when revived, will continue to work in vacoum and after a few seconds or minutes will stop again. Therefore, the author leckled to adopt a more physiological approach by increasing the contents of the cavities. It is known that an in crease in the contents although not maximal is an adequate impulse to search contraction, as long as the large last and the contents although and maximal is an adequate impulse to extend the contents.

heart is capable of responding to stimulation. In the second case injection of blood and salt solution into the left ventracle rather than the right was indicated for a definite reason. Insufficient contracting force of the recently revived heart and the pressure behind the injected solution would have been insufficient to overcome the resistance provided by the capillary netw rk in the lungs and nly in annificant amounts would have reached the left side of the heart By miecting these solutions directly int the left ventricle even the first and compara tively weak contractions of the heart re-established the blood supply t the vitally important brain centers and thus provided an antishock effect. In addition the increased volume output of the left ventricle adependently improved the coronary blood flow

When blood and other liquids are to be transfused into the right chamber the needle should be in serted into the lower part of the flourth left untercostal space one finger's breadth from the left margin of the stemum. This site will prevent injury to the intercostal neutrowaceular bundle and the internal mammary artery. The left ventracle will be entered when the needle is inserted in the same later space and from 2 5 to 3 cm to the left of the left margin of the stemum. Journel Garrie Marzia M.D.

JOAPHE GARRIE M.D.

De Weerdt W: The Influence of Sex in Transfusion Reactions (Influence du sexe sur les reactions transfusionnelles) Rev beige sc settl 945 5 144

Attention a directed to the role of the age of the donor and of the recipient in the Incidence of transitusion reactions. De Montia and Delhays in 193 found transitusion reactions in 8 pp ere cent of female to female to tensitusions in 8 p age event of female to the female to make transitusions in 8 pp ere cent of male to female to make and in 19 pp er cent of male to make. Hustin and Reny in 194 studied 624 transitusions, and found transitusion reactions in 173 per cent of female to female transitusion in 194 per cent of male to female transitusion in 194 per cent of male to female in 63 per cent of female to make.

The author has compiled data on 666 transfusions given by the Belgian Red Cross in 1943 and has grouped them according to the sex of the donor and the recipient a follows

	Trans-	le- schete	Par- centage
Female to female	88	±8	5 3
Male to female Female t male	5 90	35	3
M le to male	37	47	9.8
Total	666	5	

When grouped as to transfusion indications (neoplasms, infections anemias) more reactions occurred in the patients who had primary blood discretists.

The author believes that more research is necessary to determine the significance of the sex of the donor and of the recipient in transfusion reactions. C. Province Kirrux, M.D.

## SURGICAL TECHNIQUE

#### OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Crocs, E. J. Schullinger R. N. and Shearer T. P. The Operative Treatment of Decubitus Ulcer 4nn Sure., 1046 123 53

The authors present a method of primary closure of decubitus ulcers in young paraplegic casualties Given the same back care postoperatively as the par anienc without bed sores the results seem to be quite as satisfactory as in patients with unbroken normal skin. The method seems to be applicable to the largest steral ulcers. With rare exception, the results may be obtained by a single stage procedure. Careful preoperative preparation and evaluation are just as important as is the technique of the operation itself

The operation is performed without anesthesia Complete excision of the ulcer including the pen pheral scar tissue and the base is essential Curvi mear incisions are made on each side of the defect and flaps are raised sufficiently to close the excised area. This is done by rotating the flaps on each side toward each other. Fine nonabsorbable sutures are used. Postoperatively pressure dressings are applied. Penicillin and sulfadiazine are administered when indicated BEYLLING GOLDHAN M.D.

#### ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Damrosch, D S.: Chemoprophylaxis. J Am if 4ss 1046 130 121

In November and December of 1944 a controlled program of chemoprophylaxis against hemolytic streptococcus infections which were then of epi demic proportions was employed in three small naval training schools

In the month of November significantly fewer streptococcal infections occurred in the groups re cerving sulfadiazine prophylactic treatment (in duly doses of 1 gm) than in the control groups. During this period sulfadiazine resistant Group A beta hemolytic strentococci were absent in one school and present only in small numbers in the other two schools In December however with new trainers there was a progressive fallure to prevent streptococcal infections in the treated group. The failure was related to the increasing prevalence of strams of Group A hemolytic streptococci which

showed resustance to sulfadiazine in vitro WALTER H. VADLER M D

Adamsn, D and Smith F The Role of Chemotherapy in Wounds and Surgical Infections. 1 # S# # 1946 123 70

For the past 2 years the authors have been jointly resiged in a study of the effect of bacteriostatics in fresh trauma and pre-existing infections for the

National Research Council of Canada. The object of this investigation has been to determine as far as possible the practical value of bacteriostatics used topically or systemically and both prophylactically and therapeutically in fresh trauma and pre-existing infections. The work has been done in civilian hospitals and the laboratories of McGill University A uniform surgical technique was adapted to the individual case so that the chief variables were the type of bacteriostatic and method of application

The following points summarize the authors

The nature age and extent of any injury or in

fection profoundly modify the value of any antibiotic substance Adequate surgery is more essential in the treat

ment of trauma than are chemotherapeutic substances

The mere presence of bacteria in a wound is by no means synony mous with injection

Bacteria tend to persist in a healing wound up to the time of complete and final epithelization without clinical signs of infection

Progenic streptococci regularly disappear from wounds and pre-existing injections treated with sulfonamides or penicillin Most other wound pathogens notably the staphylococcus pyogenes, bacillus proteus vulgaris pseudomonas pyocyanea and clostridium welchi persist in the presence of chemotherapy without necessarily producing clinical infection

Bacteria in wounds were a far greater hazard in presulfonamide days than at present despite our inability to sterilise a wound completely

Topically applied penicillin has not proved as effective an agent as sulfathuazole probably because of its rapid disappearance which makes frequent exposure of the wound necessary. Its routine sys termic use in a large ward with normal personnel is much more burdensome than that of the more convenient sulfonsmides

It seems certain that bacteriostatics keep the contaminated wound from becoming an injected wound This they probably do by prolonging the important lag period restraining free bacterial multiplication during this time and allowing elaboration of the natural barrier to microbic in

All this is facilitated by immobilization and oc clusive compression dressings which are changed infrequently

Hypersensitivity reaction from topically applied sulfonamides is a highly controversial issue. The authors have seen such little evidence of it with in frequent dressings that they consider the risk en turely unimportant.

There is no convincing evidence that the bacteriostatics which have been used significantly influence

the pseudomonas pyocyanes or bacillus proteus 520 vulgaris in a wound. This remains one of the out standing unsolved problems. Both the unreserved condemnation of bacteriostatics and their endorsement as "miracle drugs are the results of completely uncritical judgment. The truth as usual, lies somewhere between these two extremes. As far as traums is concerned the most efficient of the bacteriostatics is, at best, only an adjuvant to adequate surgery

In chronic surgical infections surgery is para mount. In scute localized infections surgery and chemoth rapy are interdependent. In acute spread ing infections, chemotherapy is the immediate

Melensy F L., Johnson, B. A., Pulsaki, E. J., and Colonna, F. The Treatment of Mixed Infec necessity tions with Penicillin. J Am. If An 946 30

In the treatment of surgical infections with peni cillin t is of the utmost importance to have a complete picture of the bacterial flora of such infections and to know whether the organisms present are susceptible, indifferent, or antagonistic to penicillin Attempts should be made to eliminate acrobic gram negative, nonsporeforming bacteria, which have a destructive action, before association species have developed resistance to penicillin

P-chlorophenol is the most effective antibacterial agent against gram negative organisms, of the presagents against gram regarder organisms, or are presently available antiseptics so far tested. In a concentration consistent with safe clinical application, p-chlorophenol was bacteriostatic and bacteriocala for all the gram negative organisms tested whereas o-aminoactrinie hydrochloride and 5 nitro a furaldehyde semicarbasone were not effective against the

The individual strain susceptibility of the gram pseudomonas pyocyanes negative organisms isolated from any given infection should be tested for the nhibitory action of para chlorophenol, 9-aminoacridine 5 nitro a furaldehyde semicarbazone streptothricin and streptomycin, since the sensitivity of different strains within the same species as well as the sensitivity of different species varies greatly All of these agents are com patible with penicillin and may be combined for local application to nected wounds. They may be incor porated in a carbowax propylene glycol base for local application and prolonged action in wounds

## Leacock, A.: Penkelliin for Chronic Undermining Ulceration. Brit II

The case reported here is that of a 32 year old soldier who developed a large abscess in the left arm following an injection of T. A. B. vaccine. Despite free incision and drainage subsequent pockets occurred and had to be increed. Undermining of the edges took place with the typical sones about the edges described by Melency The edges were excised and the sinues opened t give a large flat would Plaster immobilization for one month resulted in a grad

ual extension of the ulcer so that the involved area use extension or the meet so that the lavoived area covered most of the posterior surface of the arm. Various bacteriostatics were unavailing. Zinc perox ide was not obtainable. An anaerotic hemolytic are was not consumance. An anaerouse accessive streptococcus staphylococcus aureus and pseudomonas pyocyanez were isolated from the wound on

Seven and one-half months after the initial injec tion the lesion was treated with local penicifin (100 units per cubic centimeter) enough to keep the dressings wet. After 48 hours the penicillin sensitive organisms had disappeared and in 5 days improvement was marked. The processors diminished under 1 per cent acetic acid dressings Epithelization overed more than half of the area and Thierich grafts were applied to the remainder

The literature is discussed and the lesion is dif ferentiated from postoperative cutaneous gangrene. The author believes that penicillin applied locally may be more effective than sine peruside and may replace t.

## Wie-Chang Chui Miscellaneous Pharmacologic Actions of Citrinin. J Leb Clis. M 946 3 17

Citrinia is the antibiotic substance produced by the molds, penicillium citrinum, aspergillus terrent, and aspergillus candidus. It is also found in a flowering plant, the crotalaria crispata. It is an organic acid but has not been synthesized. It is stable, and can be autoclaved at 15 pounds of pressure for so minutes without loss of antibiotic power It has a fairly high antiblotic action on most gram positive bacteria but, unfortunately it is rather toric for higher animals. It has been reported as useful as though weaker than penicillin in the local treatment of sore throat of the common cold, and of abscesses. Nothing however has hitherto been reported about its local effects, possible injuriousness to the mucous membranes and skin, and its systemic effects and absorption from various regions especially after local applications.

Proposed concentrations of citrinia sodium in sprays, lotions and cintments for local application to the nucous membranes and the skin were not found to be demonstrably irritating or injurious however the slight or moderate irritation which they produced was not objectionable as indicated by tests in animals and human beings. Concentra tions higher than those proposed caused definite protoplasmic irritation or injury but this was temporary and readily reversible.

Systemic absorption of citrain, in animals recelving high concentrations and doses by Instillation into the nose or mouth is practically negligible.

Blood concentrations of from 1,4000 to 31000 citrinin were demonstrable after the introduction of high dozes of climin into the ligated coopings and stomach and all portions of the intestine of rats and also after intramuscular injection.

Rapid intravenous injections of catrinin in doses of from 1 to 100 mgm. per kilogram caused in mediate, though temporary depressor effects, which increased with the dosage this was due presumably partly to direct cardiac depression, and partly to perpheral vascollatation. The highest doses used could produce dangerous sustained depression. Slow intravenous injections of citrinin however had no roth effect. A reversal of the depressor to pressor action occurred in atropinized animals

The average bacteriostatic concentrations of cumain in broth were: 16 000 for the staphylococcus arrent, and 1,0,000 for the streptococcus hemo-lyteus. The antibacterial action was unaffected by human serum, increased by fresh human urine, and decreased by heated urine. Experimental staphylococci infection in mice was not prevented with high doses (one-half the toric) given intraperitoneally SAUPUE KAIN M D

Otton, C. T: The Use of Tantalum Oxide, Type 400, in the Treatment of Wounds. Indust 11 1945 14 949.

This article is a preliminary report of the author a capetinese with the use of tantalum oxide type 400 Doning the war, tantalum for surgical purposes was in great demand in the form of sheet, foil and wire with probably its most successful surgical application in cranioplasty Of all the metallic implants it has the highest resistance to corrosion in vitro and in vivo Furthermore body reactions to it are strictly minimal.

Discussion with metallurgats revealed that the bealing properties of the tantalum metal must be due to the oxide coating of the tantalum which is stways present. Therefore tantalum oxide powder was prepared in such a way that it was free of all flooddes and alkaline substances. As a dusting powder it is extremely soothing to areas of the skin which have been chafed or irritated It is easily strillured by heating at a temperature of 310 degree F in a dry oven and repeated sterilizations do not affect it. It is a material which can be kept early at hand and used in a perforated top glass bottle a powder blower or sometimes by dumping it out of an open container and spreading with a sterile amilicator.

Indications for use of tantalum oxide include whited finger nails chemical burns diaper rashes weeping tesions it can also be used for surgeon a force, for intravaginal application and as a pack by for sockets of freshly extracted teeth.

The danger of secondary contamination due to retressing is practically eliminated by its use. Relief of pan is attributed to the tight sealing off which the tantalum oxide crust produces.

STEPHEN A ZIEWAN M D

Buckia, C. W Bronstein, B., Hirshfield J W and Pilling M A.: In Vitro Action of Streptomycin on Bacteria. J Am. M Ass. 1946, 30 64

Streptomycin has been shown to be effective against a variety of gram positive and gram negative bacteria both in vivo and in vitro Before it can be used rationally in treating disease an evaluation of

dose intervals and sizes and determination of the bacterial susceptibility must be carried out. There are definite in vitro differences in bacterial sensitivity to streptomycin and within a given species strains may vary from extreme susceptibility to high re sistance The blood concentration of streptomycin reaches a peak soon after parenteral injection and then falls gradually to zero. To use the drug ra tionally one must determine if a high enough con centration is being maintained with reference to the sensitivity of the particular strain of bacteria isolated Frequently a smaller dose or longer interval between doses may be sufficient to maintain a blood level more than ample to inhibit the in vitro growth of the invading organism On the other hand these studies may indicate the need for larger doses given at more frequent intervals

This study had a threefold purpose (1) to determine the sensitivities of several species of bacteria to streptomycin (3) to correlate these sensitivities with the serum concentration of streptomycin that may be maintained in patients and (3) to determine whether the bacteria investigated developed a resistance to streptomycin in vivo

Bacteria were isolated from 38 patients with various infections such as peritonitis, empyema septicemia, infected wounds and burns, urinary tract infections and pelvic abscesses. The urine or nus was cultured before and at intervals during treatment with streptomycin. Each organism present was isolated in pure culture but complete identification of all the bacteria was not made following organisms were identified escherichia coli, aerobacter aerogens, pseudomonas aeruginosa. alpha and beta hemolytic streptococci and the staphylococcus. After the organisms were obtained in pure culture they were screened for their sensi tivity to streptomycin following which their sensi tivity over a narrower range was determined. The action of streptomycin on anaerobic organisms was not determined

The authors describe their method of screening to determine the approximate sensitivity to streptomycin, and a method to determine sensitivity value within narrower ranges than those possible with the twofold sensi dilution method.

It has been found that the parenteral administration of 500 000 S units of streptomycin will maintain as serum concentration of from 10 to 15 units until the end of 4 hours. Theoretically, then all bacteria reported in this article with a sentitivity of 8 units or less would be inhibited over a period of at least 4 hours by a parenteral injection of 500,000 S units of streptomycin.

Two hundred and twelve strains of bacteria were tested for susceptibility to streptomycin. The majority of the strains of excherichia coll, proteus vulgaris aerobacter aerogenes staphylococcus, and streptococcus were susceptible in vitro to the blood concentration of streptomycan that can be main tained in the average patient over a 4 hour period when he has been given 500 000 S unit dosages of

from 5 to 8 S units per cubic centimeter of blood. The majority of strains of pseudomonas aeruginosa Investigated were found to be very resistant to streptomyche. Resistant strains of a given bacterium were isolated from patients subsequent to the isolation of sensitive strains. The assumption is that resistant strains developed from the sensitive strains. Diphtheroids were found to be either very sensitive or highly resistant to streptomycin.

#### ANESTHERIA

Wilson, G. H: Military Aspects of Early Analgoria and Anosthosia Current Rev. Lineals, 946, 5

The instructional approach to the military aspects of early analgena and anesthesia at the Medical Field Service School had to be basic enough to in cloid all of the important phases of the subject, and at the same time show the well trained anesthet ist the problems he would encounter in forward anestherias. This article discusses the overall problems involving analgena and anestherias in the combat areas.

The basic factor which determined the analyzaic or anesthetic agents used was their availability. The drugs available to relieve pain were eugenol, acctyl salicylic acid codene sulfate morphne utilate and morphine tartrate. The two narcotics available were phenolarbilat and sodium amytal. The morphine syrette proved invaluable in the combat zone che-shall grain of morphine tartrate was desolved in 1½ c.c. of fluid placed in a tube with a rubber disphragm and needle and kept terile with a cultu lold shield. This simple morphine tube simplified infections in the combat area.

Morphine was contrainducated in head injuries lung irritation from war gases heat cramps conditions resulting in amora and respiration depression and conditions in which the symptoms had to be observed to determine the necessity of operative intervention. Stress was laid upon the use of

morphine to relieve pain.

The anesthena used forward of the evacuation hospitals had to be simple safe portable, and rapid in action control Proceine hydrochloride was the agent of choic f r nerve block. Inhalation agents were lim ted to ther and chloroform was used as a reserve agent. The instructions concerning the use of i travenous anesthesia had two purposes First to keep medical officers I formed and p-to-dat concerning the fficial opinion of the Army Medical Department o th use of pentothal sodium Sec ond to give basic facts about pentothal sodium to those physicians who had little if a y knowledge of the drug. Care must be taken not to niect pentothat int an artery The da gers of this drug were enumerated. It was considered hazardous in cases of morphine overdosage, shock, infection of the neck, cervical or sublingual infections, in operations with great blood loss t those involving the airways Th

methods of resuscitation were enumerated. The nee of analeptic drugs was discouraged.

Spinal anesthesis had little value in the advanced medical units during active campaigning but as used in the clearing stations. Whenever available inhalation anesthesis with positive pressure apparatus was preferred for serious cheet injuries. General inhalation anesthesis was slow to give adequate relazation for intra-abdominal surgery and pertotal sodium was used more frequently than any other anesthetic agent by both the British and Americans

in the many forward installations.

Beecher H. K. Pain in Men Wounded in Battle.

4xx 5xxg 946, 3 96.

Two bundred and twenty five freshly wounded men in the combat zone were studied for this report. Attempts were made to correlate the pain with the extensiveness of the wound and to question the routine employment of morphine in these wounder patients. Consecutive cases were observed with no eslection other than that they had one of five kinds of wounds chosen as representative extensive peripheral soft itsue injury compound fracture of a long bone a penetrated bedd a penetrated choice and a penetrated abdomen The patients chosen were clear mentally and were not in shock at the time of overstelonize.

The findings were as follows 32 1 per cent had so pain 25 6 per cent had slight pain, 18 6 per cent had moderate pain and 23 7 per cent had severe pain.

Patients with penetrated abdomens had by far the most pain, possibly because of the spilling of blood and intestinal contents into the peritonal cavity. Of all the patients considered, only onefourth, on direct questioning stated that their pain was severe enough to require pain relief therapy.

Data were enough to require pain reases using the solution of the administered by rote and not according to the patient's needs. When morphine was occasional to the intravenous method was considered optimal to avoid the possibility of long delayed acts during periods of peripheral circulation shock. Morphine should not be used in nervous or manifest or hysterical states to allay fear or to promote steep for these purposes small does of barkturates have been adequate. Morphine should not be given in shock, unless pain is present in hypothyroidism, in the presence of dystanction of the luver or when even a mino deeree of anous causts.

Delayed morphine poisoning has occurred in battle casualties when the peripheral circulation was sluggish or loactive as 1 might be in patients who

are chilled and have low blood pressure

The treatment of morphine poloning lockeds the placing of a tourning t, internatiently looseed proximal to the site of the injection the percentage of a tourning t, international order of a oris by oxygen administration and artificial respiration and the intravenous administration of atropace (gr. 1/160) or ephedrine (gr. 1/1) is central situation.

Likewise was father an excitation of the animal. Likewise with the evipal when a immistered alone 35 mpn with the evips; when a iministeren sione 23 mgm were required to induce a narcosis of 34 mnutes while 50 mgm lengthened the natcoile period to 70

minutes. With the mephedine preparation, however the narcosis appeared sooner lasted much longer and was much deeper with more complete muscular relaxation. In fact, if 30 mgm per kilogram of menhedine were administered to the subject previ ously, the as mem, of evenal, which produced nar cosis lasting for an average of 34 minutes resulted in narcosis lasting 74 minutes or more than twice as long and with the aid of mephedine 14 mam. of exical became sufficient to induce the parcotic state.

In the succeeding studies with evipal used intra venously on rabbits the same potentiation on the

part of mephedine was observable.

In order to test any potentiative effect of mephedine on the local anesthetic power of procaine hydrochloric acid the corneal reflex of the guines pig was used This was induced by touching the cornea at sec and intervals with the Frey brush, from a to 10 such stimuli usually being sufficient. Procaine solutions in dilutions of 0.5 to 10 per thousand were instilled into the confunctival sac and retained in contact for a or a minutes, the anesthetic action beginning at strengths of o.5 per thousand. Menhedine given subcutane ously in doses of from so to so mem per killocram and synchronously with the instillations of proceine induced corneal anesthesia, frequently interms, even with the smaller dose of membedine (so mgm per kilogram) which of itself does not induce any evidence of such loss of sensitivity and with the noneffective strength of procaine (o 7 per thousand solution) Similar effects were observed in subsequent experiments with rabbits as experimental animals, and there is httle doubt left as to the potentiating power of mephedine on proceine hydrochloric acid with regard to its local anesthetic properties.

Group 3 To investigate the danger of damage or even death to the patient from reflex effects on the heart, respiration, or vomiting reflex, the rabbit was chosen for the experimental animal. It was tracheot omized and chloroform vapor was insufflated back ward from the cephalad stump of the traches through the pharyngeal and nasal passages and the resulting responsive effects on the beart action and respiration were recorded by kymographic tracmes. The same technique and tracings were produced after the endovenous perfusion of 1 mgm. per kilogram of a solution of mephedine in such a manner that the animals received 33 mgm. per kilogram of this drug when the reflex characteristics of these tracines. before the injection of mephedme, had entirely disappeared. Therefore taking the reflex irritation of chloroform vapors on the nasopharyngeal area as typical of all induction irritation reflexes of the other anesthetics and such reflexes as typical of all the reflexes incident to general anesthesia which are dangerous to the life of the anesthetized it seems evident that mephedine administered in advance of the inhalation anesthesia, is capable of depressing or even annulling all of the dangers arising from irritation of the upper respiratory tract.

Mephedme likewise seems to obviate the danger our respiratory and cardiac reflexes due to rough handling or pulling on a nerve during the operation. For this study the exposed sciatic nerve of the rabbit was stimulated electrically it being found that all evidence of such reflexes began to decrease with the perfusion intravenously (within a space of 7 minutes) of 7 mgm. per kilogram of mephedine, and that all trace of such reflexes disappeared with higher doubles

Likewise in the case of the vagus reflexes, mephe dine showed itself capable of suppressing the arrest of respiration and of the sudden hypertension and cardiac disturbances incident to atimulation of the

central stump of the severed yagus nerve.

Identical results were induced in the nerve of Cyon of the rabbit, stimulation of which normally leads to such a sudden and severe bradycardia and fall of blood pressure the necessary dote of mephedine in this instance was 14 mam, per kilogram.

Although mephedine does not entirely abolish the carotid along reflex it does attenuate such refex and thus promises to obviate such incidents as arise dur ing operations on the neck and floor of the mouth. These incidents are not always suppressed either by such anesthetic agents as evinal or by deep general inhalation anesthesis.

The author also investigated the reflexes due to pulling of other mishandling of pedicles and other forms of attachments of the organs. As a typical reflex he chose for study that produced by traction on the mesogastrium and suspensory ligaments of the stomach. This was accomplished by laparotom ising the animal (rabbit) and attaching a forceps to the stomach then closing the abdomen, so that the atomach could be subjected to traction from the outside Again the tracings showed that the consequent respiratory and cardiovascular reflexes could be abolished by the perfusion of to mgm. per kilogram of mephedine into the marginal vein of the

rabbit within an bour's time.

Before concluding this section of his studies, the author reports some studies on mice. They had nothing to do with the suppression of reflex responses by mephedine but were practically related to them. They concerned the primary or induction excitation of the animal as produced by other types of anesthet ic agents, of which he chose evipal as being typical. Six mice were injected endoperitoneally with a per cent solution of evipel, up to dosages of so 40, 60, 80, 100 and 120 mgm per kilogram. Of these dosages, all except that of so mgm. produced violent excita tion in the injected animal there were also clouic convulsive attacks followed by depression and ataxis. Forty milligrams produced convulsions and ataxia, but not narcosis and the animals recovered after about 20 minutes 60 mgm, or more caused narcosis and death in from 45 to 100 minutes so mam had no effect whatever Six other mice, 30 minutes previously had received subcutaneous injections of 3 mgm. per kilogram (1 per cent solution) of mephedine, in these, so mam per kilogram of evipal induced narcosh without excitation within 10 minutes, which lasted several minutes 40 mgm. or more produced death in narcoals without excitation.

Group 4. Mephedine in therapeutic doses exerts scarcely any or no action on the respiratory and cardiovascular systems but in large amounts it con stantly brings about a lowering of the blood pressure and a reduction of the amplitude of cardiac contrac tions and of the respiratory frequency These effects are however found with endovenous administra non, but not with subcutaneous injection nor with very slow endovenous perfusion even in large doses. For instance with an endovenous perfusion of 60 mem. of mephedine per kilogram in a rabbit accom plished within a space of 60 minutes the accompany ing tracing did not show any substantial modification of the respiration however 10 minutes after perfu mon of a rabbit with 60 mgm of mephedine per kilogram and per hour the tracing (revealing also the cardiac function) showed a lowering of the arter al blood pressure of about 30 mm of Hg and a diminution of the amplitude and frequency of res piration without any evidence of disturbance of the heart action. This however, tended soon to return to normal, so that at the end of 60 minutes (during which period 60 mgm per kilogram has been admin istered) all of the functions appeared to be perfectly

In conclusion the author desires to call attention to the fact that mephedine exerts a spasmolytic action on all smooth muscle (vascular bronchial, and intestinal) which effect deserves the attention of the Surgeon.

Allen F M Crossman L. W, and Lyons, L. V t Intravenous Procaine Analgosia Current Res Anesth. 1946 25 1

The purpose of this work was to use intravenous procline in the widest possible variety of panful conditions, the fundamental basis being that the great majority of palms are associated with local mammation or edema. Thus, procaine diffusing through specially permeable capillaries may produce analgena of the nerves in these tissues without

important effects elsewhere in the body At first the original method as suggested by Lundy was adopted, with a o r per cent proceine solution in physiological saline solution. The results of Lundy Gordon, and McLachlin, and Bigelow and Harrison were confirmed Subjective disturbances of over doses were dizziness blurred speech, or mental con lurion. The literature suggested epinephrine as the antidote for respiratory symptoms of intoxication and intravenous barbiturate for intoxication m the form of convulsions but the authors saw few of these complications. In the group of obstetric cases in which procaine was infused intravenously, this method created an optimistic impression that it might prove to be the ideal obstetric anesthesia and the fulfillment of the quest for the prevention of pain during childbirth A barbiturate was siways administered as preliminary medication reports were given in detail illustrating the use of intravenous proceine in such conditions as nucleus pulposus gangrene bed sore, and angina.

The authors modified the Lundy technique by increasing the quantities of infused fluid and procaune by lengthening the period of infusion, by using glucose solution when saline solution might conduce to harmful edema, and by extending the range of application of the tests to all kinds of pain ful conditions. The method was found to have definite though limited value and when hypersensitiveness to procaline had been excluded by preliminary tests and when the administration was kept within the limits set by dizziness or other subjective symptoms there appeared to be no danger whatsoever.

The experience with obstetric operations was extended to ordinary surgical operations of which 2 case records were summarized as examples of the method In a hip pinning 275 c.c. of salt solution containing 2 75 gm of procume were used during the course of 1 1/2 hours and 4 15 gm. of processne were used for a cholecystectomy in the course of 134 hours The first patient remained practically unconscious throughout with wide open staring eyes and a wild expression, but later on questioning he claimed that he could remember what was said and done during the operation but that he had no pain at any time. The second patient had the appearance of normal sleep with a peaceful facial expression and im-perfect muscular relaxation. The method has the advantage of rapid and flexible control absence of accompanying injury or after effects and a high degree of safety as far as can be judged to date As soon as possible, collaborative studies will be published which will attempt to establish a more adequate basis for acceptance or rejection of the method

The infusion in higher dosage has produced a chinically new form of general anesthesia by action upon the central nervous system. It is hoped that this method will prove valuable for various purposes, but there has not yet been sufficient experience to define accurately the uses imitations or possible dangers.

MARY KARP M D

Lobachev S. V: Refrigeration Anesthesia in Surgery of the Extremities. Current Res Anesth 1946 25 22

Investigational work was done at the Skilfossoviki Institute of Moscow on the technique of refrageration amenthesia, the history and bacterial flora of cooled tissues, and the relation of the sansathesia to shock. The material consisted of roccases 87 of which were traumatic injuries 4 of genigane due to viscular diseases and 9 of septi central Refrigeration anesthesia was considered excellent in 75 per cent of the cases good (slight pain on handling the nerve trunks) in 22 per cent, and poor (addition of ether required) in 3 per cent Postoperative complications occurred in 12 cases 4 developed wound infections. The mortality rate was 3 per cent, 2 patients succumbing within 23 hours to a high stage traumatic amputation of both highs complicated by brain injury and a third pa

tient dying from milary tuberculosis of the lungs months after the operation.

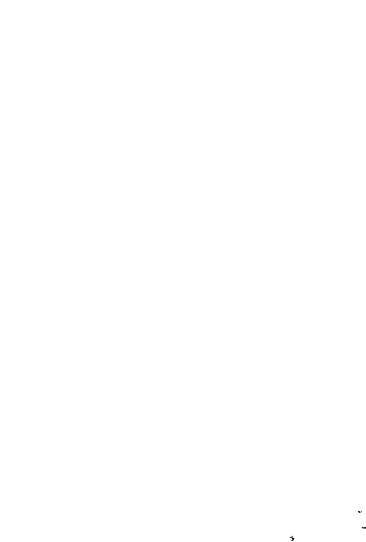

The tourniquet site selected was encased in ice for from 15 to 50 minutes, and then the tourniquet was applied Soft elastic rubber was used for this purpose the width of the rubber making no difference. The extremity was lifted prior to the application of the tourniquet in order to drain away the blood. The limb was then placed on a leather sheet filled with ice or snow and this was covered with another thick layer of ice or snow extending to from 5 to 10 cm. above the tourniquet. It was found that the temperature of the deep structures at the site of the incision was between plus 5 and plus 10 degrees C when the anesthesia was sufficient for surgical inter vention. More intensive cooling caused irreparable damage to the tissues, while higher temperature resulted in unsatisfactory anesthesia. Without a tourniquet the cooling was unequally distributed The cooling time needed was from 90 to 120 minutes fo the thigh, from 60 to 90 minutes for the leg and from 45 to 60 minutes for the arm and the forearm.

The temperature of the stump gradually returned to normal an hour after the tourniquet was re leased. After the stump was dressed it was covered with fee packs for 8 hours and the sutures were removed 12 or 13 days postoperatively as the healing was somewhat retarded because of the reduced metabolism of the cooled tissues.

It was found that pain sensibility of the limb was the first to disappear on cooling followed by loss of temperature semation, and finally by loss of tetrile senses. Histologically the tissues examined during refrigeration did not differ from those of normal controlled tissues

Primary suppuration was rarely found in solt of the injuries contracted in the street. The beteriological studies showed that the growth of indecorganisms was inhibited. The pulse was not altered even in serious cases but respirations were accelerated. The temperature remained mormal in that part of the body not refrigerated. There was no increase of palor sweat. Cynosis during the operation. The patient usually responded to stimell more actively as soon as refrigeration was effected. Apathy and somnolence gradually disappeared.

- The advantages were summarized as follows
  1. No anesthetic drugs are introduced into the
  system
- 2 There is a local reduction of temperature which counteracts the traumatic shock by numbing the tissues and especially the nerves
- 3 The application of the tourniquet and the cooling of the limb retards the formation and absorption of tourns.
  - 4. Toxemia is reduced and shock is controlled.
- 5 This method has special advantages in the aged and in patients who are seriously ill with septicemia. Mary Kary M D

which then appears to be embedded in a spongy mas. Myodika ostificans may add further layers of calcium around the joint. Numerous loose bodies are frequently present, often arranged in clusters to give the so-called bag of nuts" appearance. Although considerable swelling is usually present, fever and other signs of inflammation are absent. The lenon may therefore, progress unattended until multiple fractures in the adjacent bones and a dislocation cause complete mechanical disability.

A complicating pyrathrosis may make the differential diagnosis difficult. Ordinary degenerative arthritus may be distinguished from neurogenic Joint lesions by the absence of subchoodral cyst formation in the latter. The rapid progression the severity of the lesions and if present a perforating ulcer of the foot supplement the diagnosis of tabelic arthropathy

A spontaneous fracture or a fracture after slight trauma may be the first sign of tabes GREENET S SCHWARZ, M D

Bauer G: Observations on the Technique of Phisbography Act rad at Stockh., 945, 26 577

The author who has conducted too phiebographies since 1936 reports his findings in 180 leg phiebograms of patients suspected of developing thrombous of the leg vein. The purpose of these examinations was to make possible the early therapeutic administration of heparin or dictumantly, which indeed acceeded in preventing the spread of thrombo-

Fig. N visualization of the deep venous trunks in the middle third of the lower leg, due to thrombonis Within days phiegmania alba dolens occurred

phlebitis to the thigh in all treated cases. The findings were as follows

In y3 cases the failure of the deep veins to visualize was considered evidence of thrombosts. In 67 cases there was good or fair visualization of all the main venn. None of these patients developed signs or symptoms of thrombosis subsequently Eighteen cases deplayed sectional occlassion of a vein with dilatation of the preceding vessel segment. In 27 cases single or multiple filling defects were found in 12 of the 43 cases comprising the latter two groups, good circumstantial or indirect evidence of thrombosis could be established.

From his findings the author draws the following conclusions.

1 The most reliable x-ray sign of thrombous is non-visualization of the deep virus. An apparent constriction of a visualized win to a threadlike calber represents sedimentation of the contrast material and is not significant. It occurs only if the kg is placed in the hormontal position, a position which, nevertheless is to be preferred t the vertical for various other reasons.

2 Another valuable sign is filling defects caused by nonocclusive space occupying thrombi in the vrins. These might be confused with false filling defects which are located at ramification points of the vessels. They are caused by displacement of the contrast material by reflux of the fresh blood from a side vein into the visualized vessel and are smaller than the forms.

Various techniques are discussed. The author recommends pershordil or diodrast (ag 10 50%) for contrast maternal. An acceptabl substitute is a mixture of equal parts of intron and physiological saline solution. It necessitates, however the finish of the veins with from to to so c. of saline solution in patients who experience cramplike pains in the call silter the injection. #### Pinhler G E.: The Development of Rosnigen Therapy during 50 Years Redisler, 945, 45 503-

The author remarks on the almost immediate attempt on the part of physicians in all parts of the world to turn Reentgen a discovery of the x rays in December 80g to therapeutle uses. The interest in shoreacopic examinations with the new rays in the absence of any protection or any warning sensations early led to recognized damage of the skin of the hands and faces of the investigators while in some patients the prelonged exposure time necessary for making skull plates resulted in alopecia. The discovery of this epikting effect led Freund to treat a defiguring harry news in a young gut. He reported bis results in January, 1807 and widespread use of x rays in the therapy of skin discasses followed

At the time of the discovery of x-rays the essential equipment-Ruhmkorff or Tesla colls or a static machine and Crookes tubes-was already at hand in every well established laboratory of physics (Figs and a) and hence the necessary parts were quickly available to physicians but dosage for a given procedure was unknown and there were no instruments to record the physical factors used. The ntensity of the current and the penetrating quality of the rays were estimated by holding the hand in front of the fluoroscope dosage was estimated by biological effect-erythema or epilation. Ammeter milliampere meter and aninth rometer were how ever, developed relatively soon and the intensity of rraduation and dosage began to be estimated by photographic effect or the darkening I barrum platinocyanide duce. The small olume of cu rent produced in early apparatus necessitated tremen dous exposure times, so that the tubes quickly became overheated and the rays softer. The development of the int rrupterless coll by Snook in 100x leading t great increase in volume of the current produced the modifications of the Crookes (gas) tube togethe with accessory radiator and

water cooling devices, and finally the development of the hot cathode high reason stude by Coolings in 19.3 overcome many of these early difficulties. These advances made possible autificient constancy in volume and quality of the rays to enable radiotic the constance of elects produced by the x-rays first reported by. Reentgen in March 1866, led to the development of practical instruments for their measurement and the establishment of the unit of doors the reentgen in terms of that ionization (1928).

Early iberapeutic radiation was unaltered Per the depth dose measurements in too aboving that the intentity of the x rays diminisher rapidly from the surface to the depth of the body treated and that this decrease in intensity is much less if as absorbing layer such as 1 mm of alumnous is placed on the surface led to the use of filters in Europe. When higher voltage equipment became available with the production of a greater proportion of shorter rays filtration was locreazed both as to therebers and density of the metal theorem.

thickness and density of the metal chosen.

As t became possible to produce x-rays of varying qualities knowledge of the type of ray best suited to

the condition to be treated had to be sought, and the technique of application worked out. It became generally accepted for example, that in the treat ment of ringworm of the scalp the epilation dose should be given accurately at a single sitting even though a large area is covered but in most inflam mations and malignant neoplasms the full dose assould be divided that for acute inflaminations the dosage should be very small and given at short in one and for chronic inflammations larger doses and longer intervals are indicated Bergonie and Tribondeau had found in 1904 that immature cells and cells in an active stage of division were more sensitive than those which had already acquired the adult or resting stage and 10 years later Regard stressed the importance in the treatment of maing annes of fractional doses of comparatively low intensity extending over a long period since more peoplastic cells would thereby be exposed to irradia ton during phases of mitoris Coutard used these panciples when, about 1920 he modified the treat ment of malignant tumors especially of the oropharynx and larynx to obtain a high total dose with becreased destructive effect on the tumor cells but anti relatively less damage to the overlying normal issue than had been possible with some of the pre rous methods Recent development of supervoltage equipment has presented further problems in dosage

LILIAN DONALDSON M D' Foulsen, B R.: Investigation into the Time Factor in the Roentgen Irradiation of Cancer Cells.

A round cell sercome and a certain type of mouse carenoma were irradiated by x rays of varying in tensities over varied periods of time and the result

The tumor tusue was transplanted to a homog coors strain of nice before irradiation All of the mice then received irradiation of the whole body After a period of not more than 24 hours after com petion of the exposure (depending on the expension Bent group) the tumors were removed from the mke. The tumor tissues of all mice of the same experimental group were then mixed by mincing in order to minimize the individual variations. This these mixture was transplanted into a number of healthy mice and the effect of irradiation was then encescri

(1) By the take percentage centage of animals in which the tumor grew after

(B) By the mean latent period ie the number days after which 50 per cent of the takes became Pagent a palpable tumors (The normal values s nonirradiated tumor tissue are 5 days for

roma and 6 or 7 days for carcinoma Four intensities of radiation were used 58 r min

31/min 33r/min and 1r min The delivered e was the same in all of the cases it if it for to mice with sarcoms and 1,000 r to the mice with moma. A middle dose was delivered by a single

exposure of the mice to continuous radiation of con stant intensity which varied only with the experi 53r This necessitated exposure times ranging from 20 to 1 600 minutes The principal findings were as follows

Round cell sarcoma The take percentage dropped 25 per cent and the mean latent period rose from 15 to 18 days when the intensity was lowered from 58 r min to 1 r min. The main change was sobserved at the lowest intensity which is therefore considered a critical intensity. This tumor is thus more sensitive to low intensity radiation. The most effective intensity has not been reached in the ex perment but can be assumed to he below the critical intensity of 1 r min

2 Arebs \o 2 mouse carcinoma A drop of the intensity causes a proportionate rise of the per centage takes (up to 2000) and a reduction of the mean latent period from 17 to 13 days. This indi cates that protraction reduces the effectiveness of radiation on this type of tumor \o critical in tensity was observed with this tumor

I number of hi tological examinations of both tumors was performed aft r exposure to staggered doces of x rays (in t ps of 500 r) in order to study the relation of the cell life cycle to radio sensitivity. Within the studied range only the sar coma displayed a cyclic response to irradiation Mitosis of the sarcoma cells was increased after a certain low dose of x ravs was delivered to the

The author arrives at the following conclusions Within the studied range the carcinoma becomes more radioresistant with increasing protraction probably because the cumulative effect of radia tion is more than counteracted by the recovery which takes place during the low intensity irradia

on The sarcoma becomes more sensitive to radiation with increasing protraction because of the in erceased probability that the cells are affected during the sensitive phase of their cycle. This cycle may be intrinsic (the sensitive phase being the stage of be distinged the sense process of the stage of premitors) or induced by the physicochemical action GERHART S SCHWARZ, M D

Timmes, J J: Radiation Sickness in Negataki Preliminary Report (2 Ver 1/ Bull 1946

The author in this preliminary report presents his Ane author in the production of the radiation effects resulting from the explosion of the atomic effects resulting cross one capposition of the atomic bomb. The study was begun 33 days after the initial blast It was conducted at an improvised initiat biast it was conducted at an improvised hospital established at the Chinkozen I rimary nospital estate man difficulties school a fact which explains the many difficulties encountered

in the beginning an average of 20 new cases were in the organism and daily but within 2 week a institute to the cooperation of a new cases daily. The

investigation was abruptly terminated on September 25 1015 but some follow-up reports were secured later and they were sent to S. L. Warren and Shrids Warren in charge of the Army and Navy scientific atomic bomb commissions, respectively

The explosion of the atomic bomb is associated with a sudden excessive release of pressure heat, and radiation. The effects of the pressure and heat on human beings differ in no way from those of the ordinary bomb but the release of radiant energy is something new.

The first concern was the possible remaining radicativity on the ground and in the victims. The bomb was exploded at an estimated altitude of Roo feet with the ann to expend as much as possible of the radiant energy into the atmosphere. The author buried a raw films in the bombed are attached others to various objects about the so-called enter (a true enter does not exist). They all remained negative. Later investigators with the aid of the Geiger counter, likes fe cound the area safe as the extremely sensitive instrument registers only angighbe amounts of radiation. The effect on the victims was studied by attaching a ray films to their

limbs for it hour. These too remained negative hother pound of interest was the radiation sick ness. The Japanese claimed that most of the deaths occurring during the first werk after the blast were the result of this illness. However they did not differentiate between blast vectimes and standation vectims and attributed many of the thermal burns to radiation burns. It is the author's impression that a large percentage of the early victims indeed died of the radiation effect. This is explained by the fact that most of the civilians were not in air raid shelter when the bomb was dropped Concrete walls of 2 feet theknes probably would have af foorded adequate protection.

A study of the patients themselves reveale some interesting data. All victims observed had been within a kilometers of the center of explosion.

There were only a few x ray akin burns and they were mild in character. However many rases of alopecia were seen. In some the bare starred to fall out it to 5 days after the explosion, in others about the third week. At the end of a mouth a few of the patients had already begun to grow new bair of a downy nature. In none of the cases was the loss of bair commelter.

The most important effect of the reduction was on the bone marrow the majority of the case exhibiing an aplastic type of anemia. A white blood cell count under 1,000 indicated a poor pregnosis although 1 patient with a 400 count recovered. In some instances the blood cells completely disappeared before death. Petechiae gross betworthages, increased bleefing times (diren above as minuted) thromboertopeaks and unine revealing the presence of penhulus were noted frequently.

The average newly admitted patient complained of fever malaie loss of apostite bleefling pingires and hemorrhagic diarrises. Oral changes constituted common occurrences. The tongue was of a smooth glossy appearance and the mucosal membranes showed changes varying from a simple inflammatory lesion to deep necrosis. The teeth were generally loose and easily removed by hand. Two cases of necrosis of the mandfille and 1 of north were seen. Terminal inflection particularly bronchoppenmonia, was found to be the most frequent immediate cause of death.

The prognous was difficult to evaluate. Youth and a progressive rise in the white blood cell count represented good signs.

Therapeutic opportunities were limited.

## CLINICAL ENTITIES—GENERAL PHYSIO-LOGICAL CONDITIONS

Emerson, C. P., Jr and Ebert R. V: A Study of
Shock in Battle Casualties Ann Surg. 1945

One hundred and twelve battle casualties ad mitted to a field hospital with serious abdominal deci, or extremity wounds have been studied by the street shock. Detailed of these patients were shock. Detailed of these patients were made in all cases as well as the patients were of other the hemoglobin concentration or home of the the hemoglobin concentration or home and patients were provided by the patients when a protein concentration as well as hemoglobin contradings were completed in 57 cases in 33 and either in the course of transfusion therapy or of the patients.

The atterial blood pressure was found to provide most reliable clinical index of blood volume deficiency. All patients with initial systolic pressure below 8x mm of mercury excluding those with deficient blood 1x mercury were found to have mixed levels, the deficit averaging 4x per cent of the deficient pressure of hypotension had a diminution in blood to the contract of the source that exceeded 3x per cent.

Blood volume and plasma protein measurements indicated that some degree of spontaneous hemodi letton with low protein fluid often courted in patients with low protein fluid often courted in patients addening from oligenic shock the amount of this dilution, however was small rarely exceeding coc.C. It is concluded that a normal hematocrit patient of the demonstration of a mid anomal with every blood loss has not occurred. Severe anomal patients with the patients of the demonstration of plasma to receive the patients with marked oligenia.

The majority of patients presented no evidence of an accessive loss of plasma in proportion to the red with severe abdominal wounds there with resulted in a mild degree of extraored to have been as mild degree of extraored to have loss of exercised to have been most of severe shock before admission the hospital was 63 per cent. Hemorrhage appropriate the companion of severe shock before admission patient to the department of the severe in patients with lends with uncomplicated chest wounds.

Blood volume measurements were performed preparatively and postoperately in 10 cases in order to accrition the degree of blood loss occurring in the loss in 3 patients surjectly procedures. The average concerning the procedure of the average concerning the procedure of the procedure of the average concerning the procedure of Serial determinations of the blood volume and cated that hemorrhage occurred during the course of transition therapy in 11 of 23 patients studied. This patients was encountered most commonly in patients with severe wounds of the extremites, a averaged 40 per cent of the blood and plasma transitized.

Plasma protein measurements before and after the injection of blood diluted with equal volumes of latter in the blood stream is transient and not enough to produce significant hemodilution.

The mortality incidence of all patients admitted in severe shock was 33 per cent of those whose arternal pressure on admission exceeded 85 mm, of mercury cluded the first postoperative day. The majority of deaths were due to penetrating abdominal wounds.

Case are described in which the clinical signs of shock were unrelieved in which the clinical signs of plete restoration of the blood volume to normal life shock included severe infection femous volume the central nervous system, anosic anoxia combinations of anema oligenia and long persisting with terminal signs of myocardial insufficiency.

Therapeutic indications for the use of whole blood and plasma are cited, and criteria for evaluat ong the requisite amount of translution therapy are Joseph Gutta Millon.

Brun, C. Knudsen, E. O. E., and Rasachou F. Postsyncopal Oliguria, Kidney Function and Circulatory Collapse The Cause of Postsyn copal Oliguria. Acta med. Acea. 1045, 122, 351, 436.

In the passive errect posture with a ulting board unitentional circulator; collapse occurs frequently finds is immediately followed by reduced dureity which the authors call postsynoopal oliguria. This article deals with the investigation of renal function during postsynoopal oliguna and the cause of the latter.

Sixteen tilting experiments were done all of which were complicated by circulatory collapse. The oliginal lasted from 15 to about oo minutes after the syncope the duration apparently being proportional to the fall in blood pressure. The duration apparently being proportional to the fall in blood pressure. The duration apparently being proportional to the fall in blood pressure. The duration are rose to about and the specific gravity of the drine rose to about 10 or 10 or 15 for inthe concentration and the specific gravity of the drine rose to about 30 or 10 or 15 for inthe indicate of the finding clearance (glonormal filtration) are reduced slightly caressively in the latter instance when duration was resumed there values. The urea clearance was reduced in the period

immediately after ayocope and then followed by normal values. Fluctuations occurred as in the case of inalia and diodrast clearances but they were not nearly so pronounced presumably as a result of the increased return of urea in the tubuli during the olientia.

Since plasma is cleaned completely or usury so of diodrast by a single passage through the kildneys diodrast clearance wa taken as a measure of the quantity of the renal plasma flow. Diodrast is excreted mainly in the renal tubules and only to a smaller extent by filtration in the glomeruli.

Diodrast clearance often was reduced slightly just after syncope and then returned to the initial value and the syncope and then returned to the initial value and the syncope and then returned to the initial value marked temperary rise before the fail to anomal. The filtration fraction was without significant change during the period of oligaria. Hencoaccentration occurred during syncope but after the individual had been put back to the horizontal posture there was a gradual dubtion of the blood to a temporary lower than normal level toward the termination of the study. The blood 1 ressure and pulse rate remained unaffection.

In the discussion emphatis is placed on the chance for error (lavage phenomenon) in the clearance determinations which were then corrected and properly evaluated. Thus, the glowerular filtration and read rola ma flow are found to be normal during the

period of oliguria

Ì

These findings, together with the high concentration lodge for inuite and the high specific gravity for uring point to a greatly increased realsorption of water in the renal tubules rather than to a decreased glomerular filtration as the mechanism which governs objustia

The authors then postulate that postayneopal oliguria is induced by a suddenly increased supply of antidioretic bormone from the posterior lobe of the pitultary gland, reflexly stimulated by either the cerebral anoxia or by the effect on the pressureceptor which is caused by the fall of the blood pressure

Having postulated previoush that an antidimetic hormone from the posterior lobe of the ptutary gland was responsible for the greatly increased re absorption of water in the renal tubuli which produced a portsyncopal oliguna the authors endeavored to demon trate the occurrence of this bormone

First they tred i show that the effect on the diarest is of a bum ral nature by transflusing blood from newly collapsed subject. Three of the recipil arts sustained at level fall comparable in severity and duration t the amount of blood transflused. In 4 and 16 years of severity and duration t the amount of blood transflused. The other receipts a perfect of durens fall which was thought t be du t refer action on the pitual tary gland from repeated painful ponctures during the remercians.

Since the posterior lobe bormone of the pituitary gland is proved to regulat the acretion of chloride in th. k iner. the chloride output in the urine was determined after collapse and after oligoria transmitted by transfasson. The findings were kirothel with those observed after the largerston of impedia, an antidiaretic extract of the posterior plushary lobe. The minute chloride output did not increase that the chloride concentration index fill below 1 while the plasma concentration decreased and the chloride in the surface marketly.

Finally, studies were made on a patients suffering from diabetes insipidus. These patients are assumed to have a reduced production of antidiurcus new patients of the portay proper oliginal was a mathel as in normal people but of much shorter duration. The urine choride concentration row to consider ably below the plasma chloride concentration. The same conditions prevailed after an insiphidin injection. The about period of oligoria would tend at point to an inability on the part of a patient with diabetes insipidus to produce antidioretic putular, hormone

These three series of studies taken together up get that prosymorous oliguna is conditioned by the pitulitary aland. The authors are goick to pout out that this type of oligunais probably meetry an acrom panying phresomenous to another pitulitary repulsive, first and foremost being a regulation of the tone of the capillaries. The oliguna often seen clinically is dreated to the control transficiency viz., in shock states from burns, anesthesia, and hemorrhage is designated as collapse oliqurais in contrast to portsyncopio oligunai, during which period the blood pressure is normal. Imperati L.; Malaria in the Fractice of Surgery The Inter Relationships between Malaria Infections and Surgical Diseases (La naistia in chirurgia. Rapporti ira inferiose maistica e ma lattic chirurgiche). Gise Mai del 1045, 1115-

The author was a captain in the medical branch of the Italian military forces in Sardinia stationed at first at the principal military bospital at Capilari and later transferred to Iglesias. During this time witnessed the disqueiting recrudencence of malaris in that country and gained the experience which details in part in a series of articles of which the fart in covered by this abstract. A accord artick will be concerned with the problem of surgery in the patient with malarist splecomogaly and a third will treat of surgery, in the malarial patient.

After a relatively brief discretion of his subject-including the pathogenicity of the plasmodum at information the pathogenicity of the plasmodum at information and in relation to the varying resistance of the pathent the effect of chronks malarita on the relationshothelial system and the melanocrusiation foocealistion of Henry-the authoritums to the details of his own personal views are desperiences. This discussion is again of rided into subsections the first concerning the malarial recurrences appearing as a result of surgical inputer and the second concerning the surgical syndromes occurring as manufactations of malarial infection.

In deciding on the complicity of the material plasmodium in the f brile condition of the patient

the author and his coworkers have depended as often on the leucopenia with the relative mononucleosus of malaria as on the actual finding of the parasite in the blood cells and malaria has been suspected even in continuous fevers since recurrent malaria is capable of producing a remittent continuous temperature.

The author remembers one instance of a thoracotomized pleural empyema in which after an initial favorable course a lever of a remittent continuous type auddenly developed intense and prolonged ope success developed intense and protonged treatment with quinine produced a fall in the tem perature, aithough no blood parasites were ever

The accoud part of this article discusses the cases in which the malaria itself produced surgical syn dromes resembling those of appendicitus cholecystitis or gastric or duodenal ulcer Certain elements of the true surgical picture (vomiting constipation, facies peritoneal and/or défense musculaire) were usually missing entirely and most of the other cases would not have deceived a physician experienced in the vaganes of malaria. However the author cites some dozen cases pronounced cholecyatitis (2 cases) or appendicitis by the medical department and referred to surgery in all of which but a the malarial nature of the dolor abdominalis was recognized sat infactorily and in time. Perhaps the case history disclosed malarial antecedence or perhaps the abdominal wall was not sufficiently spastic for a défense musculaire and out of proportion to the seeming amount of pain present in any event qui nine satisfactorily cured all but 2 of these cases only in a instances was laboratory help indupensable The first instance was that of an artillerist, who had been in Sardinia for 3 years. This patient had sud den violent attacks of abdominal pain, localizing to the right illac fossa, which were accompanied by fever (39 C. or theresbouts) with chills vomiting retention of feces and partially of gas, and some display of a neurotic disposition (weeping) Physical examination the following day disclosed aniosa, a temperature of 39 C rhythmic, thready pulse of 130 and a dry tongue the abdomen was uniformly spastic, retracted almost still (borboryg mi) and presented diffuse cutaneous hyperesthesia. However the abdominal spasm was not a true de fense musculaire as it was more or less equal in intensity on the two sides and could be largely in fluenced by distracting the patient s attention also the appearance of the fever had been too brusque. In addition, the patient did not look sick enough for the presence of a phlogistic process. Blood examina tion disclosed the plasmodium praccox in great quan tity Quinne did not control the fever until the accound day and even then the other symptoms per sired some abdominal pain remaining for many

The second patient was an aviator, first class who after a years in Sardinia suddenly developed intra costal pain, irradiating posteriorly and fever of 30 s.C. Quinine injections on this same day were unsuccessful and the patient was referred to surgery

under the diagnosis of acute cholecystitis. However the impression was rather that of an atopic, subhepatic appendicitis and the author was invited to examine the patient. The abdomen was found to be tensely spastic throughout and painful to palpation the temperature was 39 C with some morning remission the tongue was dry in the gall bladder region the pain was more intense and there was some muscular defense at this point neither the liver nor spleen was palpable. The topography and season suggested malaria, even though no parasites were determinable at blood examination however there were only 4 000 white cells with 10 per cent monocytes and a few hemohatioblastocytes therapy was again instituted and after 3 days the fever and pains had entirely disappeared. Here again the relatively good general condition of the patient throughout argued against a septic inflammatory

The author seems not to have encountered the phiogistic, even necrotic, processes at times, ascribed by other authors to malaria itself such as the strumitis suppurata of malarial origin of Ceballos and Gomez malarial peritonitis Demianow's appendicits of malaria, Caruso a appendicits of necrotic and gaugrenous type, or the perivasceritis perassi taria of Pepere and of Donati and he leaves open the question as to their authentically malarial character However he does cite an instance of hemoptysis in which operation did not reveal the origin of the bleeding and which he therefore ascribed etiologi cally to the malarial parasite He passed over such causes as turgor small vascular thrombosis, and the production of punctate hemorrhages capable of producing fatty degeneration to the theory of so-called neurotropism of the malarial virus wherein degen erative processes in the vegetative system give rise to vasomotor disturbances a true angioneurosa. This theory was strengthened by the author's observation of a malarial (plasmodium praccor) asphysia and paracathesia pallida bilateralis of the feet which cleared up on a regimen of quinine antispasmodics (atropin) and hot applications

Among the involvements of the nervous system have also been those resembling an ascending poly neuntis even involvements of the cord such as monoplegies with loss of reflexes and amyotrophies one of the author's patients, apparently as a sequela of malaria developed a rather pensistent neuritis of the radial nerve with medicolegal implications

The observation of the author which seems to be unique in the literature, is that of a tertian malarra with concomitant tumefaction of the testicle and epididymis without involvement of the endovaginal serosa or cord. The swelling and pain which was present disappeared gradually following cessation of the febrile attack, the detumescence being too rapid and complete for a pyogenic or other phlogistic proc ess, and seemed due solely to the malarial infestation.

In conclusion, however, the author warms against a too ready acceptance of what might be a surgical condition in a malarial patient as an exclusive mala

ral condition and he cites a instances one a reptured appendix and the other an intestinal perforation in a patient with typhoid fever in which operative therapy was deferred because of prejudice toward a malarial etchology of the abdominal pains. The patient with the ruptured appendix recovered later following operation while the patient with typhoid lever did not.

Wasier E.; A Chromaffin Tumor Simulating Graves Disease, 4ct med sc d 1045 25 1

Tumors arising from chromaffin tissue are very rare. About 100 cases have been described in the literature. Eighty of them had their source in the suprarenal glands, while the remainder arose from the paraganglia Eighteen cases of extrasuprarenal chromaffin tumors have been reported in the literature. In several cases the tumors have given rise to characteristic choical manifestations the patients being subject to attacks of headache a sense of pressure in the epigastrium palpitation of the heart excessive sweating coldness and pallor of the I mbs and a high blood pressure. In the intervals between attacks the blood pressure would be normal and the patient would feel well. Belt and Powell have given this group of symptoms the title of the suprarenal sympathetic syndrome nature of the duesee ha often been overlooked in these cases.

in account of a mininterpreted case with pice ochromocytoma originating in the right celusc ganglion is presented. A man age 49 had been well until 314 years ago when he developed a disease characterized by palpitation of the heart, excessive weating and nervousness which required hospital care in several occasions. During his first hospital tay the basal metabolism was 143 per cent the tube 8 and the blood pressure 176/113 there was enlargement of the heart, and albumin in the unne and the latter contained erythrocytes and hyaline and granular casts. During his stay in the bospital the blood pressure was 100/ 12 184/112 170/120 and 116/114 and the basal metabolism ranged from 146 to 120 per cent. A diagnosis of Graves' disease and nephritis was made and following preoperative therapy a thyroidectomy was done. The surgeon wa a doubt as to the diagnosis at the time of the operation and his histological examination of the excised gland showed no changes characteristic of Craves disease

The attacks of palp tation of the heart and excessive sweating returned. During the second stay in

the hospital the blood pressure varied between a 30/149 and 155/90 but no relationship between it and the pattent' symptoms was noted. The basel metabolism on four occasions was 140, 150, 116 and 105 per cent. The diagnosis was still considered thyrotosicosis with hypertonia.

Upon his the distry be became work and death occurred with signs of a substachoold hemoritage. Postmortem examination revealed the pheochromocytoma in the right celling ganglion, a farm hemoritage arterioselerous and arteriolar aclerois, and enlargement of the heart. Analysis showed that the tumor contained less adrenalin than the tumors in several other cases investicated by the much more several other cases investicated by the much more

exact biological examination.

It is of special interest in this case that it was interpreted as one of Graves disease. The diagnostic mistake is of interest for two reasons. In the first place Graves disease was suspected in some of the cases of chromaffin tumor published earlier. For thermore Belt and Powell drew attention in 1914 to the similarity of the syndrome of certain cases recently described as "nongolterous hyperthy roldism to the suprarenal sympathetic syndrome In the second place it is interesting that the basal metabolism was increased in this case not only because such an increase was misleading to the dug nosis, but also because it provided matt r for thought concerning the cause for such an increase. According to Cohen in 1917 adrenally increases the metabolism by stimulating the action of the sympathetic system. It has been found that pa tients with chromatin tumors are sympathicotonic, and it is natural to assume that in these cases an increase of the basal metabolism depends on an mereased production of adrenalin Hitherto the manifestations observed of chromaffin tumors have included a rise of the blood pressure, tachycardia, excessive sweating coldness of the limbs glycosuris, and hyperglycemia. To these manifestations one may add an increase of the basal metabolism which JOHN E. KARABIN M.D. will also be found
